FOR THE SESSION 1840—41.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

INTRODUCTORY LECTURE.

IN approaching any new subject of enquiry, gentlemen, there are certain points concerning which the enquirer should always be careful to satisfy himself. He should comprehend, distinctly, what it is that he proposes to learn; its subject-matter, and its objects; he should consider whether he is about to adopt the most easy, direct, and effectual means for obtaining his purpose; and whether he is qualified, by the possession of the requisite preliminary information, for pursuing his enquiries with intelligence and success. To these points, and to some others, as they are connected with the duties with which I have been entrusted in this College, I wish briefly to direct your attention on the present occasion. It will be my endeavour to furnish you, at the outset, with clear notions of the nature and the ends of that branch of study upon which you are now about to enter; to explain why it is taught, and in what degree it may be taught, by oral discourses; to point out to you what may reasonably be expected from me, and what, to render my attempts prosperous, will be required on your parts. Something also it is expedient that you should know respecting the general order and arrangement of the course; and a short explanatory comment upon some of the terms that we shall constantly be employing, will clear the way for the succeeding lectures, which forming more strictly than the present a part of the series, will also be more strictly didactic in their character.

The subject of our study is that wonderful thing, the animal body—and more particularly the human body; its construction and qualities; its actions and its sufferings; its derangements; its decay.

In this most interesting, and surely awful study, you have already advanced a certain way. You know the outward form and fashion of the body: you have investigated its internal composition and structure: you have learned what is known of its various endowments; the uses and the actions of its several parts.

This amount of knowledge is indispensable to your further progress. It forms a portion only of what you desire to learn—or rather it is a preparation for the ends you are seeking. To the student of natural theology, indeed, it would, in itself, be sufficient and complete; and who can enjoy the privilege which each of you has enjoyed without becoming, even involuntarily, a student of natural theology? Who can look into the mechanism of this intricate but perfect work, and contemplate the evident marks of exquisite contrivance, of which it is full—the endless examples of means adjusted to ends, of prospective expedients, of compensation for inevitable disadvantages, of direct provisions for animal happiness and enjoyment—without the deepest conviction of the power, and wisdom, and benevolence of its Maker? But beyond, though not above, these higher objects of a diligent examination of man's bodily fabric, we have another and still a noble end; and it is my business to take you one step nearer to that end. Hitherto you have heard of structure and of function. Henceforward our theme must be of health and of disease. Of health, that we may understand disease; of disease, that we may, under Providence, restore health. Our objects are to preserve the one;—to prevent, remove, or assuage the other.

What then do these contrasted terms denote?

Health we regard as a standard condition of the living body. But it is not easy to express that condition in a small number of words; nor is it necessary. My object is to be intelligible rather than scholastic : and I should probably puzzle myself as well as you if I were to attempt to lay down a strict and scientific definition of the term health. It is sufficient for our purpose to say that it implies freedom from pain and sickness ; freedom also from all those changes in the structure of the body that endanger life, or impede the easy and effective exercise of the vital functions.

It is plain that health does not signify any fixed immutable condition of the body. The standard of health varies, in different persons, according to age, and sex, and original constitution ; and in the same person, even from week to week, or from day to day, it may shift and vary within certain limits.

Health, again, does not necessarily imply the perfect integrity of all the bodily organs, and is not incompatible with great and permanent alterations, and even loss of parts that are not vital : as of an arm, a leg, or an eye.

If we can form and fix in our minds a clear conception of the state of health, we shall have no difficulty in comprehending what is meant by disease, which consists in some deviation from that state ; some mode of action, or of being, or of feeling, different from those which are proper to health.

I use the word *disease* generically. Various terms in our language bear nearly the same meaning ; and endeavours have been made to appropriate some of these more distinctively. Thus the word *disorder* has sometimes been applied to simple derangements of function, where no alteration of structure is seen, or can reasonably be inferred to exist ; while the term *disease* has been restricted to maladies that run a definite course, or to such as are attended with appreciable change of texture. I see no great utility, but, on the contrary, some risk of confusion, in tying ourselves rigidly down to such distinctions. Indeed, we cannot always make them. During life it is often no easy thing to determine whether the parts, of which the functions are disturbed, preserve their integrity of structure or not : and even when the peccant organ is placed before our eyes after death, and the most careful scrutiny fails to discover in it any faultiness of texture, there may still be ground for suspecting that some material change, too subtle for detection by our senses, may have been wrought in its finer and more delicate organization. I shall take care to point out to you, as we go along, the cases in which we can trace organic change, and the cases in which we

cannot ; but, for the sake of simplicity, I shall call all deviations from the healthy standard, whether of function or of structure, by the generic term disease ; and to avoid the perpetual and tiresome recurrence of the same word, I shall not scruple to employ the several terms disorder, complaint, malady, distemper, illness, as synonymous with the term disease.

The number of these deviations from the standard of health, (in other words, the whole number of *diseases*), if we include all their differences in kind and in degree, is truly infinite ; and the first thing requisite towards investigating the laws that govern their phenomena, is, that we should break them into groups, and dispose them according to some principle of order.

Now there are various methods in which this first broad classification of diseases might be framed.

The most cursory examination of the animal economy suffices to shew that it is made up, not merely of separate parts, but of several distinct systems. There is one set of organs for the mechanical circulation of the blood ; there is an apparatus expressly designed for exposing the blood repeatedly to the air ; a system for regulating the movements and the feelings of the body; another system for receiving, preparing, and appropriating its nourishment ; another for the elaboration of matters that are useful or essential to its functions ; another system for carrying off its impurities, and for removing its superfluous or effete materials ; another for the continuance of the species.

Now each of these systems is liable to changes of structure and interruptions of function, peculiar to itself ; and these peculiarities must be taken into account. whatever may be the order adopted in treating of diseases in detail. But I shall not divide the subject, as some have done, into diseases of the circulating system—diseases of the respiratory system—diseases of the nervous system—and so on ; for this, among other reasons, that there are many forms of disorder that affect all these systems in common, or simultaneously, and comparatively few that are strictly confined to any one of them.

Neither, in the lectures which I am about to commence, shall I classify diseases according to the several *tissues* of which the animal frame is composed. In speaking of diseases in general, it will, indeed, be both proper and necessary to explain in what manner the same morbid process may be modified by the nature of the special tissue affected. But the entire body is more or less penetrated and pervaded by several of these tissues together, so that no useful or lucid arrangement of diseases could be founded on this basis.

Nor shall I attempt to construct a nosological system by grouping together certain sets of symptoms, and calling each set, in its collective form, a disease.

To say the truth, I shall consider convenience and usefulness, in framing my plan, rather than an appearance of scientific precision ; and if I make one principle of arrangement more prominent than another, it will be that which relates to the anatomy of regions—the place and situation of organs. At the same time I shall not omit to borrow in part·from some of those other plans to which I have just been referring.

Before, however, we treat of the nature of particular diseases, it will be requisite to give some general account of the different ways in which the various parts of the body are liable to be altered in structure, or disordered in function ; and before we speak of the *signs* of particular diseases, it will be proper to take a general view of symptoms, and of their ascertained relations with the several forms of altered structure ; for doubtless you are aware that, although diseases are not *constituted* by symptoms, they are, in the living body, *disclosed* by symptoms. Sometimes the symptoms are outward signals which alone reach our senses, and through which internal changes declare themselves, and we then have to decipher and interpret those signals. Sometimes we *see* the morbid changes themselves, on the surface of the body, or in parts within our view. Some internal changes we can appreciate as surely by the touch, or by the sense of hearing ; and of some we infer the existence from alterations in the chemical or in the sensible qualities of the natural excretions.

After death diseases are often to be traced, by visible changes of structure in the internal parts of the body. These changes are extremely interesting, as illustrative of morbid processes : they throw light upon what is past ; they afford some guidance for the time to come. But, for obvious reasons, those signs which reveal diseases during life are, practically, of chief moment. In truth, the great object of our art is to prevent the disclosure of the others. The instruction afforded by the dead body comes too late to be of use in that particular case.

I have already intimated that the morbid conditions from which the symptoms flow, are not always to be detected, either before or after dissolution. Neither, when they are detected, is their connexion with the symptoms always evident.

Besides inquiring into the modes in which the various organs and textures of the body may be spoiled, and into the signals or symptoms by which the presence of disease may be ascertained, it will be expedient to premise something, in a general manner, of the *causes* of disease, both with a view to its cure, and to what is much better, its prevention. We shall also find it very useful to institute a short enquiry into the different ways in which death may take place—the different processes of dying.

There is one morbid condition or process, to which all parts of the body are liable, and which contributes so largely and so frequently to alterations both of texture and function, that it claims our especial attention when discussing the more general facts and doctrines of pathology ; I allude to that change, or series of changes, which we comprehend under the term *inflammation*.

It will be necessary, therefore, in the preliminary part of the course, to give a general account of inflammation ; and this account must chiefly be drawn from those of its phenomena which are most familiar to us— which we can see and handle ; those which we witness when disorder is seated in or near the surface, in the skin, in some of the mucous membranes, or in the subjacent cellular tissue. Then we shall pursue the examination of its peculiar phenomena as they are presented in the other tissues of the body— the mucous, serous, fibrous, parenchymatous, muscular, and nervous tissues ; and here the *general* principles of treatment applicable to inflammation may be laid down, with the modifications required according to the tissues interested.

In this part of the course may also be conveniently discussed the modifications of inflammation, and of morbid conditions generally, by the influence of certain *diatheses*, or peculiar dispositions of the body. Some constitutional morbific tendencies we shall find to be innate or hereditary ;—such are the scrofulous and the cancerous dispositions : others, again, are plainly acquired, as that in which the whole system is tainted for a longer or shorter period by the venereal poison.

Hæmorrhages, also, and serous accumulations, or *dropsies*, as they are liable to occur in all parts of the body, require to be treated of generally, before they pass under our notice in the list of particular maladies. There are certain facts and reasonings common to all inflammations, to all hæmorrhages, to all dropsies. By combining these " generalities" into one comprehensive statement, we help the memory, avoid needless repetitions, and find room for the exposition of principles.

Diseases themselves, in the mass, are sometimes distinguished according as they are *local*, or *general*.

Taking these epithets in their popular sense, we should say that local diseases are those which occupy a definite portion only of the body ; general diseases those which pervade the whole body.

But let us endeavour to obtain clear notions upon these points.

Certainly there are many diseases which occupying a definite portion only of the body, leave all the remaining parts, and the system at large, healthy both in texture and in function. Such diseases we have no hesitation in calling local.

Again, there are many other diseases which occupying a definite portion only of the body, yet occasion a manifest and serious disturbance in the functions of various other parts, and (it may perhaps be said) of the whole system. Inflammation of a small portion of the frame may give rise to much secondary or symptomatic fever ; but here also we properly speak of the disease as being local ; the secondary general disorder results from the local and primary, follows it in point of time, and subsides upon its cessation.

But there are still other forms of disease which shew themselves, not like inflammation now in this and now in that part, but in many or most parts of the body *at the same time.* I will take the complaint called purpura, characterized by the universal appearance of purple spots, as an example of what I mean. It is in truth a hæmorrhage affecting many or all the tissues of the body simultaneously. For this reason it is commonly regarded as a general disease.

But if we look somewhat closer into the matter, we shall, I think, perceive that most, if not all, those which have been thus reputed general, are, in fact, reducible to the class of local diseases. The fluids are as much parts of the body as the solids ; and if it be true, as I believe it is, that the essential and primary change in purpura is a change in the blood, its characteristic phenomena will be apt to present themselves wherever there is blood circulating —that is, throughout the whole system. The disease is local inasmuch as its seat is in that particular fluid, the blood : it appears to be general, because the morbid blood is every where present.

The same observations apply to a large class of febrile contagious diseases ; to that state of the general system which is sometimes called anemia ; also to certain spasmodic affections, where the seat of the actual disease is in the whole nervous system.

What are called general diseases, therefore, are those in which the whole of some one system that pervades the entire body happens to be similarly deranged. Whether diseases can ever be truly called general in any more strict or absolute sense than this, is much to be doubted.

I have mentioned dropsy as a malady which, like hæmorrhage or inflammation, may occur in various parts of the body separately. It may also extend at once to all parts capable of receiving and retaining serous effusions : *i. e.* besides filling the large serous cavities, the effused fluid may occupy the universal cellular tissue. But even this apparently general dropsy will be found, upon careful investigation, to resolve itself, in most cases at least, into local disease within the thorax, or the abdomen.

The diseases which, in the sense now explained, may be called general, I shall arrange among the diseases of those parts of the system from which they have been ascertained, or may be presumed, to flow.

The first part then of the course will embrace an outline of general pathology, with an especial reference to those morbid conditions which fall to the care of the physician. In its relations to surgery, and to midwifery, pathology will be more particularly taught by the respective professors of those distinct though kindred departments of medicine. Do not however imagine that I take no interest in these ; or that there can be any thing different in the principles upon which the several branches of pathological knowledge are founded. The truth is, that you cannot, if you would, separate the one from the other. You can neither understand what may be called medical, without learning much which as strictly belongs to surgical pathology ; nor can you be ignorant of either without being in many important respects deficient also in the other. But the open field of pathology is of wide extent, and though we may, and must, survey the whole, its artificial divisions, its enclosures and allotments, will be cultivated best, and most improved, by a division of labour.

Afterwards, separate diseases are to be described and considered : all such, at least, as admit of being individualized, or presented under a definite shape. And here. I repeat, I shall chiefly pursue an anatomical order, as being comprehensive, and inartificial, and as tending to facilitate diagnosis. The diseases of parts which lie near each other are the most liable to be confounded.

I shall begin therefore with the diseases of the parts that appertain to the head and spinal cord ; and then proceed in succession to those of the parts belonging to the neck, the thorax, and the abdomen ; to those of the joints, the muscles, and the skin. I shall not hesitate however to deviate from this order whenever, by doing so, I can promote your convenience or advantage.

With that portion of the course which relates to particular diseases, I shall also interweave certain pathological considerations, applicable not so much to the whole body as to the several great systems of which it is made up. Thus, when I come to the brain, I shall speak of the functions peculiar to the *nervous system,* and of the obstructions and disturbances to which those

functions are obnoxious; by way of preface to a detailed examination of the various affections of the several parts of that system. Before discussing the diseases of the chest, I shall bring before you, in a general view, the manner in which the great functions of *respiration* and of *circulation* are liable to be impeded, or otherwise disordered. As preparatory to the consideration of the diseases of the abdomen, I shall treat, in the same way, of the functions of *nutrition ;* and of *waste,* which implies an interruption of those functions.

Still there would remain certain diseases, which would not necessarily find a place in this arrangement, inasmuch as their seat is uncertain, or only guessed at. Ague is one of these. Cholera perhaps another. It is quite unimportant whereabouts in the course such maladies are considered. I feel no concern about any imputations of imperfect or clumsy arrangement with which the plan that I propose to adopt may appear chargeable. I had rather not be cramped and hampered by attempting what abler heads than mine have failed to achieve, and what, in truth, I believe to be impossible, a complete and methodical system of nosology. My object will be to furnish as much instruction and information as I can, in the way that seems most likely to be practically useful to you.

Ague I shall venture to include among the disorders of the nervous system ; and with it, the important subject of malaria will necessarily engage much of our attention.

The great questions of infection and contagion I shall consider in connexion with continued fever, which I rank among that remarkable class of diseases, the contagious exanthemata of Cullen.

Of sympathetic and of hectic fever, I must speak when upon the subject of inflammation.

This, then, is a sketch of the method I propose to follow. In the earlier lectures, with the general pathology, I shall endeavour to lay down principles. To these principles I shall continually refer, as occasions offer, both in those prefatory remarks with which I purpose to introduce the diseases belonging to the several great systems that contribute to form the body ; and also in what I shall subsequently have to say concerning those diseases themselves in detail. In this way I hope to combine the advantage of repetition, which was the peculiar advantage of two short courses in a season, with that of greater completeness, which forms the recommendation of a single extended course. The same great advantage of repetition—or I should rather say of recapitulation—will be farther aimed at in the stated examinations of the class.

Such being a summary account of the topics to be embraced in the ensuing series of lectures, and of the order in which I hope to pursue those topics, it seems proper that I should now say a few words in explanation of the scope and objects of the course. The prospectus informs you that it will comprehend the *Principles and Practice of Physic.* What is the true import and promise of those words?

By the *principles* of medicine are meant those general truths and general doctrines which have been ascertained and established, slowly indeed, and irregularly, but still with considerable precision, by the continued observation of attentive minds throughout the entire progress of medicine as a science. These principles I profess to teach you. The *practice* of medicine, or the particular application of those general facts and doctrines, I shall *describe* to you ; but I cannot profess to *teach* it in this room : nor can you learn it, except in a very imperfect sense, from my description of it. It is the science that I shall here endeavour to unfold. Skill and facility in turning that science to useful purposes I am unable to impart. These are qualities that do not admit of being communicated from one mind to another. The practice of physic, like every other practical art, is to be learned by its repeated exercise ; by habit ; by carrying its various acts into direct effect again and again ; or, if they happen to require no manual dexterity, by looking on, and seeing them done again and again. There is this capital difference, however, between the art of healing and some other arts : that the blunders of early attempts may be both grievous and irremediable—may chance to spoil the goodly and precious machine they are intended to repair. There is this also peculiar to our art—that it proceeds upon observations made at the very time when its exercise is wanted ; and that it requires *skill in observing* as well as *skill in acting.* You will find, what, perhaps, previously to positive trial, you might not suspect, that the senses – the eye, the ear, the touch—however sharp or delicate they may naturally be, require a special system of training and education before their evidence can be trusted in the investigation of disease. I do not know that these views are capable of being rendered plainer by illustration ; for you must have observed a similar distinction between the science and the art in various other branches of human knowledge. The principles of navigation may be thoroughly comprehended by a person who scarcely knows a sail from a rope, and who would not be trusted, nay who would not trust himself, with the management of the simplest boat. A man may master the beautiful science of astronomy—may acquire the power of working with ease its sublimest and most abstruse

problems — and yet remain in complete ignorance of the method of adjusting or using a telescope, and unable to ascertain for himself the position or movements of a single star. But place such a person night after night in an observatory—let him notice and imitate the proceedings of some one already skilled in examining the phenomena of the heavens—and he will soon acquire the requisite tact and facility himself. Just so it is with that branch of knowledge with which we are concerned. It is in the wards of a hospital, or in the domestic chamber— it is among the sick and the dying — and there alone—that you can either thoroughly or safely learn to practise physic.

In what, then, you may fairly ask, consists the value or the use of lectures on the practice of physic, if the practice of physic cannot be taught by lectures?

The main object of systematic lectures, explanatory of the principles, and descriptive of the practice of medicine, is to prepare the hearer for observing to the best advantage the actual phenomena of disease, and the power of remedies over it. They are intended to fit him for seeing with intelligence —to enable him to read, and understand, and interpret, the book of nature when it is laid open before him—in short, to qualify him for clinical study. One man shall travel into a foreign land, knowing nothing beforehand of its scenery or its climate, of its natural productions, its manufactures, or its works of art, and ignorant alike of the manners, customs, history, laws, and language of its inhabitants; another shall visit them after having furnished his mind with information on these subjects by reading, and by conversing with men who have already passed over the same ground. Supposing the visit to be limited in each case to a certain, but not long period of time, and I need not ask your opinion as to which of these travellers will reap the greatest crop of enjoyment and of profitable knowledge from his journey. Not less striking is the difference, in point of instruction and of interest, perceived by different students, upon their first admission to the bedsides of the sick, according as they have been well or ill prepared for the multiform spectacle of bodily suffering then disclosed to them. There are persons, indeed, who seriously, and I make no doubt in perfect good faith, warn the student against bringing to the contemplation of disease any preconceived opinions; who tell him that he must come with a free and unprejudiced mind, and see, and note, and judge of all things for himself. I also would have him exercise, and ultimately abide by, his own judgment; but surely if every man were to depend upon his own unassisted observation for his knowledge of disease, every man would be mar

vellously ignorant, and the *science* of medicine would stand still, or cease to be. " If no use be made (says Dr. Samuel Johnson) of the labours of past ages, the world must remain always in the infancy of knowledge." In truth, a person who, without any previous information concerning diseases, should betake himself to the wards of a hospital with the design of impartially and resolutely investigating their phenomena, such a person, however clear and strong his intellect might be, would find himself, for a long time, more puzzled than instructed by what he saw around him. He would be perplexed by the shifting and seemingly contradictory characters presented by the same malady in different patients; or in the same patient at different times; and not less so by the outward resemblance of disorders essentially unlike. He could not but be confused by the multitude of symptoms that crowded upon his attention on every side; and at a loss to distinguish important facts from those which were trivial, or useless, for the chief ends of his pursuit.

The business, therefore, of a lecturer upon the *Principles and Practice of Medicine*, or, as it is sometimes worded, *the Nature and Treatment of Diseases*, is first to fix upon some order in which to treat of the various subjects comprised in his course. The simpler and less artificial his arrangement, the better. The chief use of this classification is to facilitate the recollection of particular facts; and I have already told you that if I can distribute the multifarious forms of disease in such a manner as that they shall appear plain to your understanding, and take a secure hold upon your memory, I shall not trouble myself or you with a vain search after that phantom—a perfect methodical nosology. " In all such classifications," writes Lord Brougham, " we should be guided by views of convenience rather than by any desire to attain perfect symmetry; and that arrangement may be best suited to a particular purpose which plants the same things in one order, and separates them and unites them in one way, when an arrangement which should dispose those things differently might be preferable, if we had another purpose to serve."

Having settled this framework of his discourses, the next aim of the lecturer must be to collect and arrange from the voluminous and bewildering records of medicine, and from the necessarily more slender stores of his personal experience, whatever it may seem of consequence that his hearers should know concerning each distinct form of disease as it comes before them for consideration: to state all the facts which are well ascertained, and which tend to explain its symptoms, to elucidate its origin;

to identify its nature, to direct its treatment, to accomplish its prevention : to sift the true facts from the false, the important from the trivial, the essential from the accidental : to analyze the relations of these facts. and ascending from particulars to generals, to point out those great principles and precepts which constitute the keys, both to the knowledge and to the management of all diseases of the same kind. It may even sometimes be his duty to notice and discuss mere theoretical opinions ; to express his own sentiments upon disputed and undecided questions ; and to admonish his audience against the danger of being led away by ingenious refinements, by the speciousness of novelty, or the boldness of speculation, from the more secure and settled results of careful observation improved by patient thought.

These duties of a lecturer on medicine are metaphorically, but aptly, expressed in the following passage from Lord Bacon : —

" Formica colligit, et utitur, ut faciunt empirici ; aranea ex se fila educit, neque a particularibus materiam petit, ita faciunt medici speculativi ac mere sophistici ; apis denique cæteris se melius gerit. Hæc indigesta e floribus mella colligit, deinde in viscerum cellulis concocta maturat, iisdem tamdiu insudat, donec ad integram perfectionem perduxerit."

. I may venture to paraphrase it thus : —

The lecturer must not be the ant, collecting all things indiscriminately from all quarters, and using them as provender for his discourses ;

Nor the spider, seeking no materials abroad, but spinning his web of speculative doctrine from within himself ;

But rather the bee, extracting crude honey from various flowers, storing it up in the recesses of his brain, and subjecting it to the operation of his internal faculties, until it is fit to be produced, digested, and ready for use.

Such, gentlemen, are the main objects which I shall endeavour to keep steadily in view during the series of lectures I am about to commence ; and I should ill deserve the chair I have the honour to occupy, if I did not feel the great responsibility under which I speak to you. The subjects with which we have to deal are not matters of mere speculative curiosity or intellectual amusement— to be taken up to-day and dismissed with unconcern to-morrow—but they relate to questions of life and death. The opinions you are now to form or to embrace, are for the most part the opinions upon which in after life you will confidently and constantly be acting. The comfort or the misery of many families may probably hang upon the notions that each of you will carry from this place. Therefore it is that I feel myself to

be engaged in a very serious undertaking. Doctrines and maxims, good or bad, flow abroad from a public teacher as from a fountain, and his lessons may become the indirect source of incalculable evil and suffering to hundreds who have never even heard his name. These reflections have impressed upon my mind an almost painful sense of the obligation imposed on me, by my present office, of closely sifting the facts, and of carefully examining the principles to be derived from those facts, which I propose to employ for your instruction and guidance.

But amid all the responsibilities, gentlemen, both of teacher and of learner, the profession which you and I have chosen, or which circumstances have prescribed to us, is one with which we may be well satisfied. It has its own peculiar privileges and advantages, and if rightly pursued may prove to each of us a lasting source of mental and moral profit. I have already reminded you how it brings under our minute and daily notice that most remarkable portion of matter which is destined for a season to be the tabernacle of the human spirit, and which, apart from that singularly interesting thought, is replete in itself with the materials of wonder and admiration. Our daily vocation tends also, by the constant exhibition of human pain and weakness, to awaken the best emotions of our nature, to foster the benevolent affections, and to promote the charities of social life. It affords us continual opportunities (and woe to him who shall wantonly or selfishly neglect or abuse them) of shewing kindness to our afflicted fellow creatures, of manifesting love towards our neighbour. It is free, moreover, or it may and should be free, from party turmoil and sectarian jealousy. Pain and danger are the only passports necessary to its good offices. It regards no political differences ; and the poor no less than the rich are embraced in its ministrations. Hallowed, as it ought to be, by religious motives, and by the sense of duties fulfilled, it offers its peculiar benefits and blessings without stint or scruple, to men of every religion, and to men of no religion at all. It conveys to ourselves the most salutary lessons ; teaching us in how many instances, forming a large majority indeed of the whole, bodily pain and anguish proceed directly or remotely from evil courses ; the sins of our fathers, our own unbridled passions, the malevolent spirit of others. It shews us too the uses of such sufferings, which are mercifully designed to recal men from the strong allurements of vice, and the slumber of temporal prosperity : teaching that it is good for us to be sometimes afflicted. It is full at the same time of the most solemn warnings, and speaking to us day by day of death, it reminds us that our time also is short

and uncertain, and but scantily proportioned to our moral wants and intellectual aspirations. Followed up in the true and Christian spirit of gratitude towards God, and love towards man, this noble profession is second only in usefulness and dignity to that of the servants of the church, and like it, when faithfully administered, it will assuredly become its own abundant reward.

A

CLINICAL LECTURE

DELIVERED TO THE

Pupils of the Bristol Infirmary*,

By Dr. Prichard.

AMONG the patients now under treatment in the wards of the Infirmary, there are several whose cases are worthy of particular attention.

I wish to draw your notice, in the first place, to a case of dropsy with albuminous urine, which has terminated in complete recovery. Michael Ryan, in Ward No. 5, was admitted on the 22d of June, labouring under ascites, with great distension of the scrotum and œdema of the legs, in a state of great debility and exhaustion. He complained also of rheumatic pains in his legs. His disorder had been brought on by exposure to cold. He had been working with his legs in mud and cold water in cleaning a dock. He had no discoverable disease of the thoracic organs, or of the liver. His urine was stated to be not very scanty, and of the natural colour. When subjected to heat, it was found to contain about two-thirds of coagulable matter : this was repeatedly done, and uniformly with the same result. Such was the permanent state of the urine for some time. Michael Ryan is now convalescent ; he feels himself perfectly well ; his aspect is altogether changed ; he has no longer ascites or anasarca ; not even œdema of the legs. His urine is perfectly natural ; it has been of late repeatedly subjected to heat, without displaying albumen. He will be discharged " Recovered" in a few days. Before I advert to the practice followed in his case, I shall make a few general observations on his complaint.

The kidneys, in a state of health, separate daily from the circulating fluid so great a

portion, that any considerable change either in the quantity or the quality of the urine, if it subsists for some time, must obviously exert a great influence on the physical state of the body, and on the health of the individual affected. If the quantity alone is materially diminished, some marked effects must soon follow. When the diminution is gradual, the overloaded vessels relieve themselves for a time by pouring out a part of their contents· into the great cavities, and into the cellular tissue, and the patient becomes dropsical. If the morbid influence which affects the functions of the kidneys is such as to produce a sudden and entire cessation, other results ensue. In some instances a partial relief is obtained by a copious fluid secretion into the stomach and intestines, and the patient vomits great quantities of a fluid which in its sensible properties more or less resembles urine. A well-known medical practitioner, who lived some years in this city, was thus affected. He had been in indifferent health for some time, when, after exposure to cold and fatigue, he was suddenly seized with total suppression of urine. This was speedily followed by almost constant vomiting, and he threw up, during two or three days, in large quantities, a fluid which in its sensible properties bore a considerable resemblance to urine. When this vomiting ceased, which it did rather suddenly, he became affected with stupor, and died comatose. A girl who was some years since, during many months, in the Infirmary, laboured under suppression, which was not always complete, for the catheter occasionally brought off a very small quantity of urine. Every evening she threw up a large quantity of fluid, resembling urine. The fluid ejected in these cases has been seldom examined with care. In the instance to which I have last adverted it was accurately analysed, and was found to contain urea, and occasionally benzoic acid, which are well-known products of the fluid secreted by the kidneys. It was suggested to me as probable that this female practised deception, and swallowed, in the first instance, the fluid which she was seen to eject from her stomach, and that it was really her urine. She was carefully watched while in the ward (No. 4), and I think she could not possibly have found opportunities for carrying on deception of this kind ; and had it been so, and the stomach in its usual state, the fluid would have been sometimes mixed with the ordinary contents of that organ. In another case in this Infirmary, I understand that urea and benzoic acid have been discovered in the fluid ejected under similar circumstances from the stomach. In future the greatest care will be taken to investigate similar cases.

---

* The following pages contain the substance of a clinical lecture delivered to the pupils of the Bristol Infirmary. As it explains some methods of practice which are there pursued, and which have been misrepresented, Dr. Prichard is desirous that it should appear in print, through the medium of the MEDICAL GAZETTE.

Changes in the quality of the urine are more likely to escape notice than striking alterations in its quantity; in fact, they often exist for a long time without being discovered. We have seen cases in which the two greatest deviations known from the healthy condition of the urine have existed, without any material change in its quantity or appearance; and this indicates the necessity of an accurate examination of the urine, and of subjecting it more frequently than is usually done to chemical agents. Cases of albuminous urine are well known to have occurred without any considerable change in the natural quantity of this fluid, and without any symptoms of dropsy. I have lately attended a private patient, who, without any material alteration in the quantity of his urine, laboured under what is termed diabetes mellitus. To term one of these diseases dropsy, and the other diabetes, is an abuse of words. The characteristics of dropsy are wanting in the one case, and the character of diabetes (which is an increased flow of urine) in the other. I shall term one of these affections *leucomaturia*, and the other *melituria*. In the case of melituria to which I have alluded, the patient was affected with slowly-coming-on and gradually increasing debility, inertia, anorexia with respect to all the physical appetites; latterly of impaired vision and memory. He was evidently becoming imbecile. His urine was stated to be natural in quantity and in appearance. A constantly dry skin, with thirst, and a slight gleet, gave suspicion of the nature of his disease; and his urine, on being subjected to heat, was found to contain a large quantity of saccharine matter. Leucomaturia, as I have said, often occurs without dropsical symptoms. This disease was first clearly distinguished by Dr. Blackall, about thirty years ago, who pointed out the fact that it arises from different causes from those of ordinary dropsy, and requires a different treatment; but it was to Dr. Bright, one of the most distinguished pathological anatomists of the present age, that we are indebted for the important observation, that leucomaturia is connected with organic disease of the kidneys. It is not, however, always an incurable disease, as the present case proves. The most appropriate method of treatment is perhaps not yet ascertained. Dr. Osborne, of Dublin, who has devoted his attention to this disease, on which he is acknowledged to have thrown much light, proposes to treat it principally by exciting diaphoresis, and by that method he appears to have been very successful. I have tried his plan, but have not been able to obtain the same result. It will be right to bear in mind his observation; and if the dry state

of the skin can be overcome, which is not always the case, some good result may be found to arise from the use of diaphoretics; but as the disease is often of an inflammatory nature—which we may infer from the exciting causes, and from the appearance often displayed by the blood when drawn—it is wrong to attempt its cure by stimulating sudorifics. It is only by collecting the results of experience—we may as well say at once, of experiments—on the success of remedies in the treatment of this disease that we can hope to arrive at any certain conclusions as to the method of cure; and in this point of view it will be worth while to note the means employed in the present case, of which the result has been more than ordinarily successful. I shall first observe that they are precisely the means which are generally most efficacious in the treatment of inflammatory diseases, whether of membranes or parenchymatous structures. The patient was bled twice during the first three days after his admission, and well purged with the black cathartic mixture of infusion of senna and Epsom salt, of which a dose was ordered for him three times in a day. His gums were then made sore by small doses of calomel, which were discontinued. He has from that time had no other medicine than a saline aperient mixture, containing sulphate of magnesia, with some spirit of nitric ether, and a few drops of tincture of squill. Under this treatment his progress towards recovery has been constant and uniform.

There are two patients now in the Infirmary convalescent of acute laryngitis, whose symptoms and progress you have had an opportunity of observing. One of them is George Morris, in No. 6, aged 25 years, admitted on the 25th of June; and the other, Phœbe Powells, aged 20 years, admitted July 23. In the case of Morris, acute laryngitis had supervened on a chronic disease of the trachea, which had previously lasted eight months, and which still remains after the acute disorder has been removed. The female had laryngitis complicated with extensive inflammation of the bronchial membrane: a muco-purulent rhonchus was perceptible in the respiratory action over a great part of the thorax. Both of these cases were characterised by the usual symptoms of laryngitis; a frequent shrill sharply-sounding cough, hoarseness almost amounting to loss of voice, oppressed difficult respiration, with a distressing sense of constriction about the larynx, and of breathing through a narrow and insufficient opening, which in reality is the case, since in these instances the epiglottis and its ligaments, and the whole larynx, are found inflamed

and thickened, so as to lessen materially the rima glottidis, which is besides obstructed with tough mucus.

The method of treatment pursued in both these cases was similar. It consisted principally in the abstraction of blood and the use of calomel, and these are the only remedial means which are of any importance in this disease. In both instances, being used early and perseveringly, they were speedily efficacious, although the symptoms were at first severe. Morris was bled from the arm, and the female patient had leeches frequently applied to her throat. Local bleeding is generally thought the most appropriate remedy, but when there is much arterial excitement, or general inflammatory action, it is almost useless to attempt reducing the local inflammation till that state is relieved by venesection. Even in the ordinary gastro-enteritis, which is the form of continued fever that generally occurs in this hospital, we often find that one bleeding of twelve or fourteen ounces will save the application of a great many leeches to the epigastrium, and relieve the patient much more speedily and effectually. Next to bleeding the most important remedy in laryngitis is mercury. I generally order three grains of calomel with one of Dover's powder to be taken every third or fourth hour until the gums become sore, and then to be immediately discontinued. In both of these cases the disorder, which had been but partially relieved by bleeding, gave way at once as soon as the mouth became affected; the cough nearly ceased, the constriction of the throat and sense of difficult breathing approaching to suffocation was removed, and a free expectoration followed. Tartar emetic was also given to these patients in small doses, and Phœbe Powells took one dose of three grains, which produced vomiting and some temporary relief, but it was from mercury that she derived the only permanent benefit.

Richard Gotham, in No. 6, was admitted on the 21st of July, aged twenty-five years. He is a sailor, and has just returned from Newfoundland in a miserably emaciated and enfeebled state, labouring under syphilitic ulceration of the throat, having his skin beset with large patches of syphilitic rupia, which slough off and leave ulcerous sores; there are two such ulcers on his scalp, which extend almost to the skull. He has besides, phagædenic primary sores extending nearly all round the glans. Some gentle opiates and mucilaginous drinks, with a nourishing diet, were ordered for this man during the first two or three days. On the 24th of June he was put upon the course of medicine which he has from that time continued. This was three ounces of the compound de-

coction of sarsaparilla, with five grains of the iodide of potassium three times in a day. His sores were dressed with the ordinary black wash. Under this treatment he began immediately to improve. All the sores filled up, and they are now every where nearly healed. He has become fat and healthy in appearance. At the end of a month from the period of his admission he was evidently convalescent. This relation proves that there are some cases of primary and secondary lues which are curable by means of the iodide of potassium joined with the decoction of sarsaparilla. The patient had been under no medical treatment. He had taken no mercury or other powerful medicine.

There was a case about two years ago in No. 7, which some of you probably remember, treated by the iodide of potassium alone. It was the case of a Welshman, who came into the Infirmary, having his body covered with ulcerous patches, which left scarcely the space of an inch of sound skin from his head to his feet. He had been ill three years, and during a great part of that time, according to his own statement, he had been under the influence, more or less, of mercury. He took, while in the Infirmary, no other medicine than nine grains of iodide of potassium three times in a day, and he recovered entirely in a very short space of time. These cases prove that there is a form of syphilis, or of syphiloid disease, in which the preparation of iodine, before mentioned, is very serviceable, and is, indeed, capable of affording a cure. How are we to discriminate these cases, and what is the real nature of those instances of syphiloid disease, like that which I have last mentioned, in which mercury is without any curative efficacy, and even injurious? Some writers maintain that mercury is, in these instances, the cause of the evil. We hear a great deal about mercurial disease; but those who have considered the matter in this point of view have not told us why mercury never induces any such malady when it has not syphilis or some similar complaint to begin upon. Mercury is often given here freely in severe cases of bronchitis, pneumonia, and other inflammatory diseases; but its use is never followed, in such instances, by the appearance of any syphiloid complaint. There is some mistake in the notion that such cases are instances of disease produced by mercury. After all that has been written on this subject by the celebrated surgeons of the present day, or of that which has lately passed, I know not that any writer has thrown much light upon the subject, except Mr. Carlyle of Dublin, who has set forth a most ingenious and certainly probable hypothesis, which, as I

hardly doubt, contains the real and true solution of this difficult problem, although it may yet require some modification, and more extensive evidence, before it can be looked upon as fully established. Half a century ago all venereal affections were classed under one head, and patients were salivated for gonorrhœa under the impression that they had contracted lues. Since the time of John Hunter and his immediate followers, it has been admitted that these are two distinct diseases. Mr. Carlyle maintains, and has, I think, gone far towards establishing the fact, that there is a greater number of such contagions ; that there are, at least, three diseases, each of which has its appropriate primary and secondary symptoms. Gonorrhœa is one of these : the primary disease, as every one is aware, is a specific inflammatory affection of the mucous membrane of the urethra : this is followed occasionally by secondary symptoms, which are, rheumatic affections of the limbs, and slight cutaneous eruptions, chiefly of a papular kind. Secondly, genuine syphilis has its primary symptoms ; chancres, that is, excavated ulcers with retracted edges, and a hardened base, and the secondary symptoms are excavated ulcerations in the throat, eruptions of a scaly character, or syphilitic lepra. Sometimes these are merely discolourations of the skin, or purple blotches without scabs, or easily losing them. The tertiary symptoms, as they have been termed since the time of Mr. Hunter, are, affections of the periosteum, giving rise to pains in the bones, as they are termed, and to nodes. A third and different form of secondary disease is manifested by cutaneous defœdations of a more severe kind, such as tuberculous indurations, which are often seen about the forehead. With these may be classed the disease of the skin resembling rupia, and which may be termed syphilitic rupia, and which has been well exemplified in the case of Richard Gotham. These secondary affections, which I have last mentioned, and to which must be added ulcerations of the throat and palate, are sequelæ, according to Mr. Carlyle, not of genuine chancre, but phagedenic sores, arising from a contagion different from that of true syphilis. A disease is said to prevail in Portugal, and in the ports of the Mediterranean, which is of this description, and which is much more dreaded than the ordinary form of syphilis. The primary sores in the case of Richard Gotham are phagedenic ulcerations ; and the succession of symptoms thus coincides with Mr. Carlyle's opinion. It is of great practical importance to mark this discrimination, since it appears to be a fact that the phagedenic ulcerations, and the secondary symptoms, which constitute their appropriate sequelæ, indicate a

disease that is always aggravated by mercury. It would be a fortunate thing if it should be found that this complaint, in which mercury is inadmissible, can be cured by the hydriodate of potass and the decoction of sarsaparilla ; and this, from the facts which I have mentioned, appears likely to be the case. In the two instances to which I have alluded, these remedies appeared to act as if they possessed some specific power : we may frequently observe secondary symptoms to disappear under the same treatment, but we have seldom an opportunity of tracing the disease from its primary form, as in the instance of Richard Gotham.

Cure of Chorea.

Charles Haynes, a little boy, aged nine years, came into the hospital on June 25th, and he has just been dismissed. You have all seen him in No. 5, labouring under chorea. When he was admitted, a cathartic draught, the ordinary purgative mixture of infusion of senna, with Epsom salt, was ordered for him, to be taken every morning, and this, with the addition of the shower bath, was all the medical treatment that he underwent. He immediately began to improve, and left the Infirmary, as you know, quite well. Chorea is a disease of the brain, that is, the pathological state which is the immediate cause of the symptoms, is an affection of some part of the encephalon. This does not appear obvious from the ordinary phenomena of the complaint, which consist nearly in jactitation of the limbs : but the inference may be drawn, first, from the connection of chorea with other confessedly cerebral diseases, such as epilepsy, with which it is often combined ; secondly, from the consequences of long-continued chorea, which are similar to those of epilepsy and paralysis, namely, dementia, or an obliteration of the mental faculties : it is not uncommon to see children half idiotic from chorea, and they become in time completely so, if the disease is not arrested ; thirdly, this disorder affects sometimes all the muscles of voluntary motion ; in other instances it attacks those of one side only, just as the muscles of one side are affected, either in hemiplegia, or in some cases of epilepsy : hence it may be inferred that the morbid cause acts immediately on the common centre of the motive power, which is in the encephalon ; lastly, in fatal cases of chorea, for it is sometimes fatal, there is found more or less of effusion on the surface or in the ventricles of the brain. But chorea, though its proximate cause, or the immediate cause of its phenomena, is an affection of the brain, is not discovered by experience to be most successfully treated by remedies applied to the head, such as are found to be useful in other cerebral affections. It ap-

pears that the primary cause is in some
other part of the body, and the affection of
the brain is but an intermediate link
between it and the symptoms which manifest
themselves. It is by removing the primary
cause that we cure the disease. This is often
an unhealthy condition of the alimentary
canal, and chorea may be cured in many
instances by purgative medicines. I have
seen a case of chorea which had already
induced extreme debility, and the appear-
ance of imbecility, cured by a course of
purgative medicines. This plan was
first recommended by Dr. Hamilton, of
Edinburgh, in a well-known work on pur-
gative medicines. It was pursued in the
case to which I am now referring: the only ad-
junct to purgatives was the shower-bath, and
the patient began immediately to improve,
and was soon completely well. I generally
begin the treatment of a case of chorea by
ordering a black draught every morning,
and sometimes find this all that is required.
The cases of chorea which I have found
curable by purgative medicines alone have
been those of boys: I know not whether
this may be accidental, but I rather think
not. In most instances, in females, the
nervous system appears to be too much
shaken, and the brain too much disordered,
to be thus easily curable by purgatives
unassisted, and that especially when the
disease has been occasioned by a fright.
In these cases metallic tonics are found to
be the most useful auxiliaries. It has been
the custom to use chiefly the oxide of zinc
in this hospital: we find it the most effica-
cious as well as the most easily administered
remedy of this class; it is given at first in
small doses, as 5 or 6 grains, three times a
day, which are gradually increased to large
ones, such as 20 or 25 grains. In the course
of 25 years I have seen but one or two cases
in this Infirmary in which this remedy failed.
It is worthy of note that this treatment
seems never or scarcely ever to be successful
in out-patients: the cause is obvious—a
regular and simple diet, such as these patients
have in the wards of the Infirmary, is a
necessary condition for the cure.

We have in the infirmary at present two
cases of cerebral disease, which have been
treated by issues on the scalp, made in one
instance by incision, and in the other by the
application of caustic. One of these cases
is that of a young woman, named Shipway,
in No. 2; and the other of a girl, named
Kirkby, in No. 4. Mary Anne Shipway
had been nearly twelve months in the Infir-
mary before the issue was ordered. She
was admitted on account of some surgical
complaint, and afterwards sent into the me-
dical wards: there she laboured under some
pain in the right side of the head under the pa-
rietal bone. Her disorder was treated by the

ordinary remedies, not inactively, but without
arresting its progress; it increased; the pain
was most distressing, and without intermis-
sion: the seat of the disease was apparently
the arachnoid, or the surface of the brain;
her faculties became impaired: she was at
length so demented or imbecile, that it was a
question whether she should be sent to St.
Peter's Hospital, where there are wards for
insane persons and idiots. It seemed right,
however, to make a trial of this remedy in
the first instance, and a long issue was formed
on the scalp over the sagittal suture, by
means of the alkaline caustic, which was
applied in the form of a paste. Some time
elapsed before any improvement took place
in the intellect of the patient, but she soon
obtained a remission of pain; she was still
'silly,' as the nurse and the patients in the ward
observed. However, she has now recovered
an entire possession of her faculties, and she
has scarcely any remains of the pain
which formerly tormented her: her only
suffering is for a short time after the issue
has been dressed. There seems little room
for doubt that we may soon venture to
remove it. The other case, to which I have
referred, is a patient of Dr. Wallis. I make
no scruple of mentioning it, as I am sure he
would not object to my so doing. This girl
laboured under typhoid fever, affecting the
brain. She sank into a state of complete
coma; lay perfectly insensible, passing
her evacuations involuntarily, and incapable
of being roused. She appeared almost mo-
ribund. An incision was made over the
sagittal suture, by Dr. Wallis's direction.
The patient became soon more sensible, and
is now convalescent.

This method of applying counter-irritation
in diseases affecting the brain has been until
lately nearly peculiar to the Bristol Infir-
mary. I wish particularly to call your
attention to the fact that we never make use
of it except in cases of the most severe and
intractable disease; it is a severe remedy,
though more so in appearance than in reality,
and should only be used in cases in which
all milder means have failed, or afford no
expectation of benefit. I have been informed
that in London this practice has been very
much censured. It has been represented
that we have recourse to it on trivial occa-
sions. I have been told that a metropolitan
teacher of medicine, when going through a
hospital with his pupils, has been heard to
address a patient, having some compara-
tively trifling affection, in such terms as
these: — "It is lucky for you that you
are not in the Bristol Infirmary, or you
would have had your head cut open before
now!" If any of you should chance to
hear observations of this kind, you will, I
am sure, correct such a mistake, and assure
the party under so erroneous an impression

that we never adopt the method which he censures, but in cases which admit of no other hopeful means, either of preserving life when about to be extinguished by disease of the brain, or restoring the intellectual faculties, or of curing amaurosis, or inveterate cases of epilepsy; and under such circumstances it has been found, under the blessing of divine Providence, to have been in some cases completely effectual.

AN INQUIRY INTO SOME OF THE CONSE-
QUENCES AND CAUSES OF FAILURE
OF THE

NEW OPERATION FOR THE CURE OF STRABISMUS OR SQUINTING.

By E. W. DUFFIN, ESQ.
Surgeon.

[*For the Medical Gazette.*]

WE cannot reflect on the phenomena which characterised the two last cases related in the second portion of this communication (Sept. 18) without attempting some solution of their peculiarities. In the first patient, it will be recollected, that although only *one* eye, the left, was subjected to operation, *both* eyes respectively were brought under an undue ascendancy of the external rectus, when this muscle was called into action by directing the axis of the eyes to an object placed at either side of the individual, without turning the head. When the girl looked at anything placed at the left-hand side of her, the cornea of the corresponding eye was partially buried in the external canthus, while the pupil of the right eye was not moved beyond the centre of the orbit, and *vice versâ* when the object was placed to the right of her; though certainly not in so great a degree. Her sight was under either circumstance double, and the position of the eyes that of a very unpleasant leer; but she could regard an object placed directly before her with the most perfect accuracy. In the second case, the young lady squinted with both eyes, though in no very remarkable degree. The first operation on the left eye was attended by every indication of the most complete success. At the expiration of three weeks the tendon of the adductor in the right eye was divided, and instantly the pupil of the left was turned outwards, and vision became double; even when she

looked at an object placed immediately before her. In the course of an hour or two after the operation, however, she acquired the power of directing the axes of the eyes with the utmost accuracy when the object was placed before her; but it was found, if she looked at any thing on one side of her, that then the external rectus of that side exerted so great an ascendancy as to completely turn the cornea to the external angle of the orbit, when she saw two objects instead of one. This undue action of the external rectus, however, was more marked in the left eye, that first operated upon, than in the right, in which, indeed, it now no longer exists; hence I am in hopes that in the course of a short time longer it will wholly cease in the left eye also. The facts of these two cases suggest several very important and interesting queries worthy the attentive consideration of the physiologist, the accurate solution of which would clear up much of the difficulty that attends the theory of that singular sympathy which exists between the two eyes in order that their axes may be always so directed to the same object as to render vision single. The more we investigate this subject, the more we shall be struck with the beautiful and inexhaustible resources of nature, and admire the consummate wisdom, skill, and beneficence, with which she adapts them to the accomplishment of the end in view. When the adductor muscle is cut across, and the eye liberated completely from any adventitious or other attachment that may still retain it in its unnatural position, the abductor muscle, if in a healthy condition, immediately draws the pupil to the *visual* centre of the orbit; for the *true* centre of the orbit is not the natural position of the pupil when the eyes are directed into space.* In some instances, immediately after the adductor is divided, the cornea is turned somewhat outwards, and remains in this situation for a day or two, or even much longer—until, as it would appear, a reunion is effected between the divided tendon of the sclerotica, which generally takes place within fourteen or sixteen days; the new attachment being a little

* If a careful measurement be made when the eyes are completely quiescent, it will be found that the pupil is placed in a very trifling degree nearer to the canthus, than the centre between this and the outer angle.

behind the original insertion, and, what is very satisfactory, without any return of the original evil.

The first question which suggests itself is, why does not the abductor in every instance turn the eye outwards when its antagonist muscle is divided? The most simple and natural reply to this query seems to be the fact, that, in a state of health, voluntary muscles have no disposition to contract unless called into action by an effort of the will; and that when the eye is restored to the position it ought to occupy, the abductor muscle being then completely relaxed, will not draw it unduly outwards, unless that effort of the will be exerted. When, however, it does act in this untoward manner, we may argue, that having been long accustomed to exert its influence against a morbidly contracted antagonist, and other sources of opposition, it may have acquired more than natural powers of contraction. But these cease in the course of a short time, being lost either from want of practice, or from being met by an equivalent degree of resistance when a new union takes place between the divided tendon and the eyeball. Should there exist a considerable cast in the other eye, then we have an additional power from this undue contraction. We must recollect, in such case, that when the individual looks outwards to the side that has been the subject of operation, the other eye will be turned more than naturally towards the nasal canthus, and that the effort to render the axes of the two eyes in this direction more correct has been favoured by the division of the adductor or antagonizing force; hence the eye will be morbidly directed outwards, in order that its axis may correspond with its faulty companion.

But it sometimes happens, we have seen, that the eye not subjected to operation is directed outwards as well as that in which the tendon has been cut. How, then, are we to explain this apparent anomaly? The abductor and adductor, it is true, are antagonist muscles, but their actions are performed quite independent of each other. The controlling power of each is to be sought for in the corresponding muscles of the opposite eyes respectively: *i. e.* the abductor of the one, and the adductor of the other, act in concert, and modify or restrain the irregularities of

each other in all the consentaneous lateral motions of the eye that demand an effort of the will. The external rectus, for example, of the right eye, is the antagonist of the corresponding internal muscle, but its controlling power is seated in the adductor of the opposite eye; and thus it is we are enabled to direct both organs laterally, so as to make their axes correspond.

If, then, the internal muscle of the left eye be cut across, its antagonist does not contract unduly, unless from the temporary cause alluded to, because it is still in connection with its controlling power—the adductor of the right side, and the nerves which supply it with energy; and were it to turn the pupil of the eye to which it is attached outwards, the adductor of the other eye, with which it operates consentaneously, would turn the pupil of the eye to which it belongs inwards—an effect it only produces when called into action by an effort of the will. But if the adductor of the right eye is much contracted, and an obliquity exists in this eye also, then it is possible that the direction of the pupil outwards may not proceed from the cause already alluded to, but from that nervous sympathy which regulates the consentaneous actions of the two eyes; more especially when the person directs the pupils to an object placed at one side of him. It will be remembered that as the one pupil, under these circumstances, is nearly buried in the inner canthus, so the other must turn very much outwards, in order that the axis of each may correspond.

If we proceed still further in this inquiry, and examine the anatomical distribution of the nerves, we are at once struck with the omniscient foresight evinced in this particular. Were the external and internal recti muscles supplied with energy from the same source, the third nerve, the consequence would be, that when these organs are called upon to contract by an effort of the will, they would do so simultaneously, and thus the eye would remain fixed between two antagonising forces. But fortunately these muscles are not supplied with energy from the same source, the internal, superior, and inferior recti, all deriving their energy from the third pair of nerves, while the external rectus is supplied by the sixth pair.

On the other hand, were the functions of the abductors not controlled by the nervous communication that subsists between them and the adductor muscles of the oppposite eyes respectively, we should find both of the external recti to be excited into contraction simultaneously by the same act of volition ; the consequence of which would be, that both eyes would turn to the external angles, instead of the one being turned inwards and the other outwards, as nature so wisely designed.

When the eyes, then, are fixed on an object placed at either side of the individual, the adductor of the one eye and the abductor of the other act in concert.

If the internal rectus of the left eye, for example, be divided, the eye does not turn unduly outwards when the pupils are directed to an object placed at the left hand of the individual, because the left eye, in such case, acts in concert with the right, and the nervous energy by which each is respectively controlled remains entire ; the sixth nerve on the one side, and the third nerve on the other. That the abductor, therefore, should contract beyond the desired extent, when its antagonising adductor is divided, is not natural, because the muscle and nerve by which its contractions are sympathetically controlled, and by the consentaneous influence of which vision is rendered single, remain unimpaired. Besides, it will be remembered, that after an eye has been operated upon successfully, the individual is no longer capable of directing the pupil inwards ; and that consequently, as the eyes perform their functions and movements in concert, the controlling power which retains their axes parallel under ordinary circumstances, even when both adductors are divided, will have a disposition to restrain the contractions of the abductors within natural limits ; although, in every instance, they may not be sufficient for that purpose. The two muscles that contract together to produce the same movement in both eyes, viz. the two adductors, are supplied with nerves from the same source, while those which produce in each eye a different movement calculated to fulfil the same end, are supplied with different nerves ; but these nerves, it will be recollected, are united together at various points of their course in a most remarkable manner, as will presently be demonstrated. Indeed they become sufficiently identical, if I may so express myself, to perform the functions of one nerve. When, therefore, the eye is directed unduly to the outer angle of the orbit, after the internal rectus is divided, we can only explain the circumstance by supposing that the antagonising muscle no longer meeting with the physical resistances which has rendered it unusually powerful, contracts, *pro tempore*, more than is desirable, because it is in reality the stronger muscle, although till the eye was liberated this did not appear to be the case.

The truth is, as before stated, it had to contend not only against its morbidly shortened antagonist, but also against a thickened, contracted, and perhaps adherent condition of the submuscular cellular tissue, which to a certain extent bound the eye in its abnormal position.

The unnatural position of the eye outwards, therefore, under such circumstances, is seldom of long duration ; the resistance being destroyed the cause of increased power in the muscle ceases, and in a short time the eye is restored to its natural position.

This explanation, it may be argued, clears up the difficulty very fairly, as regards the young person in whom only *one* eye was operated upon ; but it does not explain the other, in which the nomal-direction of the pupils occurred, until the operation had been performed on the second eye also. In this case it appears to me that the abductor of the left side did not evince any disposition to inordinate action when its antagonising adductor muscle was divided, because it had not acquired any undue contractile power, and was still under the natural influence of the right eye, and the nerves by which the muscle is supplied. The obliquity of vision moreover was not great, and the motions of the eye by voluntary effort were very free : hence we may conclude, that the external rectus had not been habituated to contend against any unnatural resistance, which might strengthen its ordinary powers of contraction. But for what reason, as soon as the second operation was performed, both abductors should evince a disposition, when called into action,

to draw the pupil unduly outwards, is not very clear. It is true the muscles with which they each previously acted in concord were severed from their attachments, but the nervous power by which their contractions were excited and controlled remained the same. There evidently existed, therefore, some further sympathy between the two muscles respectively, dependent upon their integrity, and this ceased as soon their attachments were destroyed, and will I have no doubt be restored when they have formed new insertions into the sclerotic coat.

There are two causes, therefore, to which we may ascribe undue contraction of the external recti muscles, when the eye is liberated at its internal periphery, and this untoward circumstance supervenes.

When it happens in the eye that is the subject of operation, we may presume it to be owing to the abductor having acquired unusual power during the continuance of the obliquity, and exerting that power as soon as it is at liberty to do so. In such case it will cease when the acquired energy ceases to exist, or the antagonising muscle becomes re-united to the sclerotica. When it occurs in the opposite eye to that which has been the subject of operation, it proceeds from the destruction of that restraint which the abductor derived from its nervous connection with the adductor of the opposite eye; the third and the sixth pair of nerves mutually influencing and controlling each other in the simultaneous lateral motions of the eyes. As already stated, if we consider the connection between the third and sixth pair of nerves anatomically, we shall find it to be in reality extremely intricate and complicated; and, as would now appear, for a very evident and important reason.

The third nerve (motor oculi), and sixth nerve (abducens oculi), both arise from the track of the fibres of the corpus pyramidale (tractus motorius). These fibres are continued through the pons varolii into the crus cerebri; so that although the sixth nerve issues from the brain, at the upper part of the corpus pyramidale, and the third from the crus cerebri, they may be considered, in point of origin and function, as a single nerve, merely separated by the breadth of the pons varolii.

In addition to this identity of origin, the third and sixth nerves communicate very freely in the cavernous sinus, by means of the carotid plexus; and indirectly through the medium of the ciliary ganglion, carotid plexus, and superior cervical ganglion of the sympathetic nerve. The first of these communications is established between the inferior division of the third nerve, which supplies the internal rectus muscle, and the ciliary ganglion; the last between the sixth, and the superior cervical ganglion; while the carotid plexus is the bond of communication between both.

But there are other causes of failure, of which it is of the utmost importance the surgeon should be fully apprized, previous to subjecting his patient to operation; that his sanguine expectations of success may not be disappointed, and his prognosis belie his practice. When, during childhood, the eyes have been repeatedly affected with strumous or other inflammation, of which, in the absence of more positive information, we often perceive evidence in the existence of nebulæ and specks on the cornea, we may find the whole of the muscles and investing cellular tissue of the eye, so extremely adherent to the sclerotica, that it would be imprudent to detach them to the extent necessary to liberate the globe in a sufficient degree to admit of its assuming the proper position, even were the rectus and membranous attachments on the exterior of the organ to have escaped the ravages of the disease, but which, under such circumstances, seldom happens. When, then, we find the motions of the eye very limited, and that the patient is incapable of bringing the pupil by an effort of his will to the centre of the orbit, having previously suffered inflammation, either during childhood, from accident, or other causes, we should consider well the probable degree of success before we operate. I have met with a few examples of this description in my own practice, and have witnessed several in that of other surgeons. In one instance, a man operated upon in Nottingham, on one eye, by my friend Mr. J. N. Thompson, and on the other by myself, the whole of the investing structures of the inner periphery of the eye were found to be thickened,

contracted, and infiltrated to such a degree, that they cut like cartilage, and required both extensive and careful dissection from the sclerotica.

Fortunately the mischief was confined to the inner portion of the sclerotic surface, so that when the eye was liberated at this part, the external muscle had power to draw the pupil into its proper situation, and the case did well. This man had two small specks on the one eye, and a nebulous opacity on the other. Notwithstanding this disadvantage, his vision was much improved by the operation, as his eyes were previously buried in an unusual manner in the nasal canthus, from which position he could move them but in a very slight degree, being only able to bring the pupils, by the greatest effort of the will, to a point scarcely midway between the inner canthus, and the centre of the orbit. His sight was defective, I imagine, not only because he could not see any object he looked at with both eyes at the same time, but because it was difficult for him to turn the eyes sufficiently outwards to admit of the object being depicted on the sentient part of the retina destined to transmit visual impressions to the sensorium. May it not happen, also, when strabismus is very marked, and the eye confined, as in this example, that the optic nerve suffers inconvenience from being slightly bent on itself; partial amaurosis being a frequent attendant on squinting.

I afterwards operated upon a lady whose right eye was turned so much inwards that it was with difficulty she could draw the pupil from the nasal canthus: this patient had been twice couched for opacity of the lens in this eye, and had, on each occasion, suffered from severe inflammation. She informed me that the obliquity of the eye had been considerably increased, and its freedom of motion much diminished, by the inflammatory attacks she had experienced.

I found the same amalgamation of muscular, tendinous, and cellular tissue in this case that I have already described. After the operation, the abductor could not turn the pupil outward, though it was able to draw it, by an effort of the will, to the centre of the orbit, and gradually, in the course of a few days, it acquired considerably more power;

from which it would appear that the muscle was not only bound down by morbid adhesion, but had also been kept on the stretch for so long a time that it had lost its contractile power: and that it was from this state of preternatural tension only, that it recovered: just as the muscular fibres of the bladder lose, *pro tempore*, their contractile power, when this viscus has been over distended by retention of urine.

Although only partially successful, as was anticipated, my patient was much gratified by the operation, as she suffered very trifling inconvenience from it, and it materially improved her sight; indeed in a much greater degree than could have been expected, considering that the eye was deprived of its lens.

The fact of the external muscle requiring time to recover the contractile power, of which it would seem that it is deprived by long-continued extension, I have frequently witnessed, and always found in such case that the patient was unable to bring the pupil to the centre of the orbit previous to operation.

A remarkable example of this occurred to me at Derby, when I was assisted by Mr. Douglas Fox, Mr. Wright, Mr. Godwin, and other surgeons of that town, who very kindly procured a large number of patients, for the purpose of aiding in making the present observations. In the case alluded to, the woman was unable to turn the pupils sufficiently towards the centre of the orbit to expose the whole of the cornea to view. Both eyes were liberated by the operation, but a considerable time elapsed before the pupils approached their proper site. They did so, however, as much as could be expected, before she left the room, and the case has since, I am informed by Mr. Fox, improved in a remarkable degree. She was almost entirely amaurotic before the operation, and recovered her vision, so as to distinguish small objects, within an hour afterwards. About ten days ago I operated on a similar case, and a week elapsed before the eye was restored to its proper site.

Another cause of failure, and one of much more importance than any yet discussed, is paralysis of the abductor, or adductor muscle. I have not seen a case exemplifying the former, but

can readily imagine the possibility of the occurrence, because 1 have seen three cases of the latter. In one of these, unfortunately, the tendon of the external rectus was cut by a friend of mine in the country ; the case being at first regarded as an example of contracted abductor. It proved, however, to be the contrary—paralysis of the internal rectus. This might have been discovered before the operation, had the surgeon been on his guard, because there were other evidences, such as slight ptosis and impaired volition as regarded the movements of the eye inwards, sufficient to point out the true nature of the case. There was, however, no loss of power in the retina ; her sight was good. She had suffered much during childhood from cerebral disease, accompanied by convulsions.

I have at present a very remarkable case of paralysis under my care, in which the eyes are both turned outwards, the left completely, although the loss of muscular power in the limbs is on the right side of the body. The affection of the eyes occurred at the moment of paralytic seizure, and singularly enough, as in the above case, is limited to the adductor muscles.

Another cause of failure is want of judgment in selecting the cases of strabismus that are proper for operation. Unfortunately, such is the mania for this operation, that all who squint are deemed proper subjects for the test of surgical skill. But there are numerous examples, in addition to those I have indicated, that ought not to be treated by this means.

A girl was shewn to me who had been operated upon, and whose eyes afterwards turned spasmodically in every possible direction. On inquiry I found she had twice suffered from chorea, and that the squint was a sequela of that disorder. At times, for weeks together, no obliquity of vision was perceptible ; the affection would then recur, and continue for an indefinite period. Her eyes were very unsteady, and it was quite evident that these relapses were local returns of her former ailment, dependent, in all probability, on disordered bowels, temporary mental or other irritation. The treatment in this instance should have been medical ; and so it should be in all cases which we are informed are intermittent, and seem to depend on

cerebral or gastric disorder, teething, convulsions, vermination, or acute disease.

The permanency of strabismus should be well established before any operation is had recourse to.

When not congenital, the disorder is, no doubt, ninety-nine times out of a hundred a sympathetic spasmodic affection, more or less evanescent or intermittent in its nature, and should for a length of time be regarded as such.

The period at which it may be viewed in any other light will, of course, vary in different individuals, and must be dependent on a multitude of circumstances, of which every practitioner is capable of judging, when once his attention is directed to the subject, and which, therefore, need not be insisted on in the present remarks.

14, Langham Place, Regent Street,
Sept. 15, 1840.

STATEMENT OF THE CASE

OF

ALEXANDER M'LACHLAN SMITH,

ACQUITTED OF A

CHARGE OF MURDER AT THE LATE
YORK ASSIZES ;

With Observations on the Plea of Insanity in Criminal Cases.

By CALEB WILLIAMS,
Surgeon to the Retreat, near York.

[*For the Medical Gazette.*]

THE trial of Edward Oxford for attempting to shoot the Queen, and the recent acquittal on the ground of insanity, at the York Assizes, of Alexander M'Lachlan Smith, charged with the murder of a policeman at Huddersfield, have given rise to many remarks on the responsibility of lunatics, and fears have been expressed in many quarters as to the danger of readily admitting the plea of insanity where individuals are convicted of atrocious crimes.

The branch of legal medicine which relates to the question of insanity is assuredly of great interest and paramount importance, both to the individuals implicated in the inquiry, and to the community at large ; and whether it affects the custody of the person, the care of the estate, or the graver question of the responsibility of individuals accused of criminal acts, the

decision in each particular instance demands the most serious and attentive consideration. With regard to the responsibility of lunatics, it has always been acknowledged in general terms, that insane persons are not accountable for their actions, and that in acquitting them of crimes with which they might be charged, the community very properly are satisfied with requiring that they should be kept in safe custody, to prevent a repetition of similar offences.

In order to substantiate the plea of insanity under these circumstances, it has been rightly held that it should be shewn that the commission of the crime resulted from the delusion, or particular form of insanity, under which the individual laboured at the time of its perpetration. In the case of Alex. Smith it will be seen, by an examination of the evidence adduced on the trial, and by other facts connected with his history, that the crime with which he was charged naturally resulted from the circumstances in which he was placed in connexion with his peculiar physical condition.

The difference of opinion which at present obtains on the subject, renders it very desirable that cases of this description, which have been the subject of legal investigation and decision, should be fairly laid before the public, more especially with reference to the members of the legal and medical professions, to whom the community are accustomed to look for opinions and decisions in cases of real or supposed insanity. The consideration and discussion to which the statement of such cases gives rise, is likely to lead to greater precision in the determination of questions, often involved and ambiguous, and yet affecting most seriously the right of individuals to property, liberty, and life itself. Justice demands that the grounds on which insanity is admitted as a plea of exculpation from punishment, or as a ground of exclusion from social rights, should be as uniform as possible.

Under these impressions, and having been called to give my opinion as to the sanity of Alexander Smith, at the late Assizes, I have drawn up the following statement of the facts of the case, and of the grounds on which my judgment was formed.

Alex. M. Smith is a short athletic man, with light red hair, of the choleric temperament, 37 years of age. He states that he has been the subject of epileptic fits upwards of sixteen years. It is ascertained that, when he resided in Stirling, he had very frequent paroxysms; and he is described by persons who had repeated opportunities of witnessing these fits as being violent and furious in his conduct, both when they were coming on, and when they were going off. In the state of excitement preceding the epileptic paroxysm he has without any provocation, and while surrounded by other persons, attempted to cut the throat of his master; and he has in the most savage manner seized his wife by the throat, so that "she could hardly disengage his gripe." It was not unusual for him, when the fit was coming on, to take off his clothes and attempt to run naked into the street; or if he had been taken with a fit in the street, to strip himself naked on the spot, if not prevented. It is also stated that, "when recovering from the fits, he was very violent, and given to strike every one about him, especially if they tried to keep him from running into the street, which at such times he always wished to do.'' One individual who lived near Smith says, that "about twelve years ago he was called in by the neighbours to assist in keeping him down in bed, where he was lying, furious, kicking at, and trying to hit those about him, and this continued a long time." His wife states, " that, in general, after a fit, till he got sleep, he was like one out of his mind, and regardless what he did." He acknowledges himself that, prior to his having fits, he was in the habit of drinking whiskey to excess ; but that since he had been so affected, he has not allowed himself to indulge in intoxicating liquors, on account of the great excitement they produced ; and the parties who knew him between four or five years ago describe him as a sober man.

When he first came to England is not known ; but early in the summer of 1839 he is found at a lodging-house for labourers at Elland, near Huddersfield, where he has frequent attacks of epilepsy—sometimes four or five fits in one day, and frequently three or four in as many successive days: the interval was sometimes a fortnight, and at no time exceeded a month. After

these attacks he is described as being very outrageous in his conduct, and "awkward to manage," so that the lodging-house keeper was obliged to take great care "not to vex him." The lodging-house keeper distinctly stated, in his evidence on the trial, that "but for the lodgers he could not have managed him;" and even with their help he was sometimes indebted to his neighbours for assistance. "The lodgers were also careful to avoid any thing that put him out; they thought him not right in his head." When he first went out into the village after these attacks, his wild appearance attracted the attention of the children; and his irascibility and tendency to violence at all times being known, he was teazed and called by a nick-name, (Alick Gingerboy), which contributed to increase his irritation; and in this excited state he has run after them with an open knife in his hand, when oftentimes it was with great difficulty the children of the neighbours escaped from him unhurt. During his stay at this lodging-house, and within a few months of his stabbing the police officer, he was twice under medical care for inflammatory affections of the brain, marked by very violent conduct, incoherent language, and sleeplessness, in addition to the other ordinary symptoms of such diseases. One of these attacks occurred without any epileptic fits. On these occasions he was treated by general and local bleedings, blisters, setons, &c. &c. with temporary relief; and in the book kept by the surgeon of the Union for that district, he was returned as labouring under "temporary insanity." When he left these lodgings on the Friday preceding the day (Tuesday) of the fatal affray at Huddersfield, he is described by one of the witnesses as being "very cross and rough," doubling his fist in the face of the lodging-house keeper, and making such a noise as drew the neighbours to the spot, where their presence had become needful for the old man's safety.

The evidence of the keeper of the lodging-house to which he then removed, and where he passed the three days and nights, previous to his going to Huddersfield, is precisely similar:— "He was in a very cruel state, that is, he was raving; he said he would pull us to pieces, cut us up and draw

us limb from limb." This person also states that he believes the prisoner did not know what he was doing during the three days he lodged at his house; that on the Tuesday morning, when he left the house, "he looked very wild with his eyes, and that both he and his wife were quite frightened of him."

He is next found in the market-place at Huddersfield, where his excited state (increased no doubt by some intoxicating liquor given him by an old acquaintance) attracts attention, and is mistaken, by one of the witnesses, for an indication of intelligence; which his ordinary appearance certainly does not exhibit. This witness says, "there was something about his bold uncompromising manner that struck me." Here, without a farthing in his pocket, he attempts to bargain for the whole of the plants on the stall of a market gardener:—he then singles out a particular plant, and offers twopence for it, notwithstanding the gardener had told him the price of it was one shilling and sixpence: he, nevertheless, assumes the plant to be his, and seizes hold of it. While he and the gardener are disputing, a police-officer comes up, and desires Smith to give up the plant to the gardener; and on his refusal to do so he is taken into custody, and conducted, with the assistance of the gardener, to the lock-up. Already in a state of great excitement, he becomes exceedingly irritated by the interference of the police officer, and still more so by the means used to take the plant from him; the policeman having struck him a violent blow on the knuckles with his staff, while the gardener (with whom he had the original dispute) was striving to wrest the plant from his grasp. In this furious state a chain is put upon him, and he is placed in the cell, where he evinces maniacal rage by talking in a most incoherent manner, making a great noise, and kicking at the door. After he had been in the cell about two hours, the police-officers go to him again; and as soon as the door is opened, he rushes out, and with his gardening knife (which had escaped the search previously made of his person) stabs the officer who had struck him with his staff. This man is mortally wounded and falls: another officer comes to his assistance, and Smith

stabs him also, and cuts him in several places. Smith exults in having "done for two" of the policemen ; and, swearing at another, says " he will do for him yet." After the knife had been taken from him, and he had been secured, he again says, " I have done for two of the b——s, and adds, " I'll do for other fifty ; then England will be free."

During the night he is heard singing : the next day before the coroner he is unmoved, and even light in his behaviour : on his way to York at one time he is "very cheerful, and converses with the police officer, who had him in charge, about horticulture," "not at all impressed with the horror of the deed he had done ;" at another he is sullen, and refuses to speak ; and, on one occasion, he is very violent. Whilst he is in York Castle, notwithstanding the prison diet and the medical discipline to which he is subjected, he has returns of the epilepsy, and frequently quarrels with his fellow prisoners.

At an interview which I had with him a few days before his trial, when he was reminded of the crime with which he was charged, and that if convicted he must suffer the extreme sentence of the law, he neither appeared to feel any regret for what he had done, nor did he express the least alarm or apprehension regarding the result of the trial. This indifference was accounted for by his subsequent statement that since he had been in prison he had had communications from Jesus Christ, one of which was made by means of *two notes applied to his breast* ; and that these communications from his Saviour had made him comfortable, and set his mind at ease, so that "he considered himself safe, let whatever would happen." He also entered into a wild and incoherent account of his views regarding the miraculous conception of Jesus Christ, the nature of the new birth, &c. &c.

During this conversation with Smith, it was evident to me that he has a very imperfect recollection of what takes place whilst he is in the state of excitement which either precedes or follows the fits ; and in several instances it appears, from incidents of his history, that his most outrageous attacks and assaults upon those about him are afterwards entirely forgotten.

It should not be omitted that a respectable chemist and druggist, of Elland, to whose shop Smith resorted for medicines to allay his nervous feelings, gave it in evidence, that having had very frequent opportunities of observing that peculiar and violent conduct of Smith, he was fully convinced that he was of unsound mind ; and so settled was the conviction in the mind of this individual, that it was to his exertions that Smith was indebted for the inquiry into his case, and the defence which was in consequence set up.

From this sketch of the history of Smith, it appears—

1st. That during the last sixteen years he has been subject to frequent attacks of epilepsy.

2ndly. That a few months prior to the affray at Huddersfield, he had been twice under medical care for inflammatory affection of the brain, and had been reported to the Poor Law Union as labouring under "temporary insanity."

3rdly. That his violent conduct and incoherent language, which preceded and followed the epileptic fits, had given rise to the belief in the minds of those who had the most frequent opportunities of observing him, that at those times, at least, he was not in his right mind, and did not know what he did.

4thly. That there was a continued state of morbid irritability of the brain, which rendered him peculiarly irascible and violent when any real or imaginary insult was offered him : this state of irascibility and violence quickly passed into uncontrollable fury, and a disposition to gratify the most implacable revenge.

5thly. That the repeated attacks of epilepsy, and the recurrence of an inflammatory condition of the brain, had impaired his understanding, weakened his judgment, and perverted his affections or moral feelings. Hence his delusions regarding the communications from Jesus Christ, and his indifference with regard to the crime with which he was charged, and the punishment which probably awaited him.

And, 6thly. That on many occasions, and particularly at any time during the days previous to the affray, at Huddersfield, any competent medical practitioner who should have examined

him, would, without hesitation, have certified him to be insane, and a proper object for confinement in a house appropriated to lunatics. It is well known that persons of his description are to be seen in almost every such establishment. They are there employed in various ways, according to their previous habits and occupations. Whilst they continue calm and tranquil, they are often clever and industrious; but their liability to become violent and furious on any slight occasion, renders them unfit to be at large. To casual visitors, and under ordinary circumstances, they present no trace of mental infirmity; but if any thing occurs to offend or irritate them, their appearance is at once and altogether changed, and they are seen to be the subjects of an overwhelming influence, impelling them to acts of ungovernable fury.

It will be admitted that to those unaccustomed to the consideration of these subjects, the case of Smith may appear to be one of those instances in which it is difficult to discriminate between the manifestations of insanity and acts of a truly sane nature; and the more so, as the homicidal act did not arise out of any illusion or hallucination, but appeared to be prompted by the natural passion of revenge in a man of violent temper. When, however, we find the most judicious medical writers, of this and other countries, and those who have enjoyed the most extensive opportunities of observation,[*] concurring in the opinion, that where epilepsy has existed it affords a strong presumption of insanity, and that " a very large proportion of epileptics are particularly subject to violent agitations of passion; that they are rendered by their physical state morbidly irascible, impetuous, and incapable of restraining the sudden expression and gratification of their desires;" and when it is borne in mind, that Smith's ordinary conduct had for many years exhibited this morbid irritability of brain, we are irresistibly led to the conviction, that the homicide act of *such* an individual ought not to be confounded under the same denomination, and subjected to the same penalty, with the crime of him who, calmly and deliberately, waits until his

victim has fallen asleep, and then cuts his throat, for the purpose of concealing his own dishonesty, or even of him whose more hasty and less deliberate commission of murder is the result of unbridled passion, and of habitually indulged evil propensities—*not* of a diseased condition of the brain, a calamitous visitation, emphatically termed by the lawyers, " the act of God."

The notice of this very important and interesting medico-legal case, would be incomplete without a record of the doctrine laid down by the learned judge (Baron Rolfe), on the subject of the criminal responsibility of lunatics. In his charge to the jury, he stated that if it was proved that at the moment of the homicidal act the prisoner was impelled to its commission by " a phrenzy, or uncontrollable fury, such as had been spoken to by some of the witnesses," the plea of insanity would be equally maintained as if proof had been given of his labouring under actual delusion.

A CASE OF SPINAL DISEASE,

IN WHICH HICCOUGH, BEING ONE OF THE MOST DISTRESSING SYMPTOMS, WAS COMPLETELY REMOVED BY INSERTING A SETON OVER THE ORIGIN OF THE PHRENIC NERVES.

To the Editor of the Medical Gazette.

SIR,

IF you consider the following hasty description of this very interesting case worthy a place in the pages of your widely circulated journal, you will oblige me by inserting it.

I am, sir,
Your most obedient servant,
J. WATMOUGH, M.D.

Pocklington, Yorkshire,
Sept. 9, 1840.

Miss H. last October, whilst dressing a sore on the hand of a poor woman, was suddenly seized with syncope, which caused her to fall on the rugged floor of a cottage: a slight convulsion followed, described by the attendants as lasting for three or four minutes. On coming to herself, she complained of pain in the back, with numbness of the legs.

Two days after, I found her labouring under severe pain in the inferior dorsal and super-lumbar vertebræ, with head-

---

[*] Esquirol, Georget, Prichard, Conolly, &c. &c.

ache, and loss of sensation and motion in the lower extremities. Leeches, bleeding from the arm, with small doses of calomel, and counter-irritation on the spine, were the means used. She cannot now, eight days from the first seizure, be moved from the horizontal position; bowels are regulated by purgatives; and slight incontinence of urine relieved by tinct. lyttæ.

Three weeks have now elapsed since she was first attacked. Singultus, which has occurred frequently, now becoming severe, cupping, leeching, blistering, with four caustic issues on the spine, were now had recourse to, together with the internal and external use of preparations of iodine, small doses of strychnia, &c. Notwithstanding, six months passed away without much alleviation of symptoms: singultus became intolerable, threatening to prove fatal rapidly. I inserted a seton over the origin of the phrenic nerves, and eight days after, these formidable symptoms ceased, sense of feeling and power of motion were restored to the legs, and, by the use of the inclined plane, with tonics, &c. my patient gradually progressed to sound health, and is now able to walk well, and travel considerable distances.

OPERATION FOR HARE-LIP.

To the Editor of the Medical Gazette.

Sir,

I beg to communicate through the medium of your journal a method of operating which I employed in a case of double hare-lip with perfect success, and which appears to me more simple, less liable to failure, and less painful both at the time and afterwards, than the common operation with hare-lip needles.

For this operation two thin plates of silver, either circular, with a small hole in the centre of each, or oblong, with two holes, or otherwise modified, according to the form of the parts to be united, are required. One of these plates is threaded by a fine three-sided needle, armed with a double ligature, knotted at the end so as to check against the hole in the plate; and, the edges of the lip having been previously pared, the needle is passed as in the usual operation, but drawn completely through with the ligature, until the knotted extremity of the latter brings up the plate firmly against the lip. The other plate is then threaded on the ligature, and slipped down to the lip on the opposite side, so as to bring the parts into proper apposition. The ligature is then divided so as to leave ends sufficiently long, which are tied down against the aperture in the second plate.
(*a a*) silver plates, with the ligatures secured so as to bring the included parts into proper apposition.

Thus a ligature, or two ligatures, secured at each extremity by a plate of silver, are substitutes for the hare-lip needles and twisted suture: the traction and pressure exerted by this means act in a more favourable direction, and the parts included are less liable to cut out than by the common method, besides which the usual dressings and auxiliary supports are more easily and more effectually applied.—I am, sir,

　　Your obedient servant,
　　　　Alfred J. Wood.
　　Surgeon, Gloucester Infirmary.
3, Barton Street, Sept. 12, 1840.

ANALYSES and NOTICES of BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'Alembert.

A System of Practical Medicine comprised in a series of Original Dissertations. Arranged and edited by Alexander Tweedie, M.D. F.R.S. &c. London, 1840. 5 vols. post 8vo. pp. 1885.

The work now before us forms the first portion of the Library of Medicine.

The first volume contains an introduction by Dr. Symonds; a treatise on inflammation, by Dr. Alison; essays on the general doctrines of fever, on

continued, and on hectic fever, by Dr.
Christison ; on the plague, on inter-
mittent, remittent, and yellow fever, by
Dr. Shapter ; on infantile gastric re-
mittent fever, and on puerperal fevers,
by Dr. Locock ; on small-pox, by Dr.
Gregory ; on measles and scarlet
fever, by Dr. George Burrows ; and on
diseases of the skin, by Dr. H. E.
Schedel, of Paris.

The second volume is on diseases of
the nervous system, and the essays in
it are written by Drs. Bennett, Hope,
Prichard, and Theophilus Thomson.

The third volume opens with the
diseases of the organs of circulation ;
all the essays on this subject being by
Dr. Williams, with the exception of one
on influenza by Dr. Theoph. Thomson,
and one on asphyxia by Dr. Carpenter.
The rest of the volume is occupied
with a number of essays on the dis-
eases of the organs of circulation, by
Dr. Joy.

The fourth volume opens with the
remainder of the essays on the diseases
of the organs of circulation, by Dr.
Joy. We then arrive at treatises on
diseases of the digestive organs by
Drs. Symonds and Dr. Thomson; on dis-
eases of the spleen by the latter physi-
cian ; on diseases of the urinary organs
by Dr. Christison ; and on those of the
uterus and ovaria by Drs. Ferguson
and Simpson.

The fifth volume contains treatises
on the general doctrine of hæmorrhage
and on its varieties, by Dr. George
Burrows; on scurvy by Dr. Budd ; on
the general doctrine of dropsy and on
its varieties by Dr. Watson ; on scro-
fula by Dr. Shapter; on bronchocele by
Dr. Rowland ; on rheumatism and gout
by Dr. Wm. Budd ; on worms by Dr.
Arthur Farre ; and a formulary, con-
taining remarks on the art of pre-
scribing, together with classed prescrip-
tions, by Dr. Joy.

Dr. Christison's essay on conti-
nued fever has the clearness and
precision which distinguish all his
writings. The points of which he
treats are the " symptoms of con-
tinued fever.— Secondary affections.—
Affections of the head— of the throat
—of the chest— of the abdomen— of
the skin.— Sequelæ.— Relapse.— Par-
tial rheumatism and neuralgia.— Par-
tial palsy.— Œdema.— Acute febrile in-
flammations.— Supervention of phthi-
sis pulmonalis.— Mania.— Prevalence,

duration, and mortality.— Anatomical
characters. — Causes. — Prognosis. —
Treatment.—Prophylaxis."

Dr. Christison defines continued fever
in nearly the same terms which Cullen
applies to fever generally. " It is a
disease in which after a precursory stage
of languor, weakness, and defective
appetite, acceleration of the pulse takes
place, with increased heat, great debi-
lity of the limbs, and disturbance of
the functions, without primary local
disorder, and without well-marked re-
missions." (Vol. i. p.125.) These cha-
racters are not invariable ; sometimes,
for instance, the pulse does not rise
beyond seventy ; and a man in the in-
cipient stage of fever has been known
to walk forty-five miles within as many
hours; but general disturbance of the
functions is less variable than any other
of the characters.

It has become fashionable of late,
says our author, to deny the existence
of synocha, or inflammatory fever, in
this country, and to suppose that ephe-
meral fever is the only example of it
in temperate climates. In the Edin-
burgh epidemic, however, of 1817-20,
it was very common ; and Dr. Chris-
tison found that for some time it formed
between a fifth and a sixth of the cases
in the Infirmary and Fever Hospital. In
some of these instances the fever had
complications, but the disease was alto-
gether divested of the typhoid charac-
ter. Some of the symptoms of synocha
mentioned by our author are, the in-
creased temperature of the patient,
raising the thermometer to 102, 104,
and sometimes 107 degrees ; the florid
colour of the blood, which is occa-
sionally so bright that the surgeon
imagines he has opened an artery in-
stead of a vein ; and an extreme irrita-
bility of the senses of sight and hearing.

Dr. Christison believes, as we do, in the
existence of idiopathic fever, but allows
that complicated cases are more com-
mon. Among the local disorders which
may occur incidentally during the
course of fever, he mentions affections
of the head—such as congestion on the
brain or its membranes, meningitis,
and a convulsive affection allied to
epilepsy ; affections of the throat, for
instance, cynanche tonsillaris, aph-
thous ulceration of the throat and
mouth, and cynanche parotidea ; affec-
tions of the chest, namely, catarrh,
pneumonia, and pleurisy; and various

affections of the abdomen; among others an obscure disorder of the stomach allied to gastritis. This disorder is supposed in France to depend on inflammation of the stomach; but Dr. Christison, with more probability, believes it to arise from mere irritation, connected with a congested state of the organ, or from functional disturbance caused by a depression of the powers of the brain. Broussais supposed that it was a true inflammation, and that, in combination with a similar disease of the intestines, it was the essential cause of all continued fevers.

Dothinteritis, again, was supposed by M. Louis to be the local cause of some typhus fever. This name, which was first proposed by Bretonneau, is derived from δοθιην, a pimple, and εντερον, the intestine, and is intended to signify an inflammation of the glands of Peyer and Brunner. In Britain it occurs only occasionally during epidemic typhus. Petechiæ are so common in some epidemics, that it is rare to find a case without them; but there is no ground for the assertion, that in true typhus, petechiæ are never entirely wanting.

In the section on the prevalence, duration, and mortality of fever, Dr. Christison shows how numerous the cases have been of late years in Edinburgh and Glasgow. " In Edinburgh, for example, during four severe epidemic visitations since 1816, each lasting between three and four years, the number of beds constantly occupied in the hospitals has varied from 120 to 150; and for some time past (Jan. 1839) the latter number has been often insufficient to meet the demands for admission." (p. 147.)

In 1837, the mere hospital admissions of fever cases in Glasgow amounted to 5387! Of the cause of this frightful prevalence of fever, and of its remedy, we have treated on former occasions.

Dr. Christison believes fever to be infectious, and has certainly brought forward very strong instances in favour of his position. Take a couple of samples. " *In Edinburgh not a single nurse escapes who remains long enough at her post.* * * * * * Of fifteen gentlemen, who held between 1817 and 1820 the offices of house-surgeon or resident clerk, in the Edinburgh Infirmary and Fever Hospital, two only escaped an attack; and during seventeen months

of the period, when the epidemic was at its height, there occurred sixteen cases of fever among ten of these, of whom five had it once, four twice, and one thrice." (p. 157.)

Dr. Christison's account of the treatment shows great candour and good sense; he discusses the effects of local and general blood-letting, emetics, cathartics, and the cold affusion, with remarkable impartiality, and his observations cannot be read without profit.

The Formulary with which Dr. Joy has concluded this division of the Library will prove eminently useful to young practitioners. Among the errors most apt to occur in extemporaneous prescriptions he enumerates, 1. the " ordering substances to be combined, which are by their nature incapable of uniting," as for instance, oil in a decoction, without any mucilage, yolk of egg or alkali.

2. " Prescribing a particular form for the compound, which its ingredients, when brought in contact, are incapable of assuming or preserving;" such as ordering sulphate of soda and carbonate of potash to be rubbed into a powder; for they become fluid when mixed.

3. Prescribing doses too large, or powders too irritating, to be conveniently taken.

4. Prescribing incompatible substances, such as sulphate of iron, nitrate of silver, in astringent infusions or decoctions; or large quantities of Goulard water in mucilaginous lotions.

5. Directing a mode of preparing the ingredients which is injurious to their qualities, or lessens their power. Thus senna has its griping tendency increased by long boiling. Under this head comes the selection of an inappropriate menstruum, such as an alcoholic one for a solution of gummy matter.

5. " Omitting the proper directions for the preparation or use of a medicine."

In the section on doses, Dr. Joy gives Gaubius's table, and Dr. Young's formula, which we agree with him in preferring: " the doses of most medicines for children under twelve years of age must be diminished in the proportion of the age to the age increased by 12; thus, for example, at two years,

$$\frac{2}{2+12} = \frac{1}{7}.\text{"}$$

The formulæ themselves are divided under eighteen heads, such as stimulants, narcotics, antispasmodics, tonics, astringents, diaphoretics, expectorants, emetics, cathartics, &c. Among the stimulants we find arnica : we subjoin the formula, as the remedy, though of considerable repute on the continent, is not in our British Pharmacopœias.

" ℞. Arnicæ Mont. Flor. ʒj. Aquæ ferv.
Oj. Stet per Semihoram. Cola. Sumat
cochl. ij.—iij. ampla ter die. (In para-
lysis, chronic rheumatism, dysentery.
Its use requires caution.") Vol. V. p. 283.

In some cases the author recommends Dr. Law's method of prescribing calomel, in the dose of a twelfth of a grain every hour, with extract of gentian. He says it will often salivate very rapidly.

On the whole, the System of Practical Medicine does credit to the tact with which the able editor has selected his contributors, as well as to the practical knowledge they have shewn of their respective subjects. The book is closely printed with a small type, so that it contains a vast mass of information within its nineteen hundred pages.

We give especial praise to Dr. Tweedie for the rapidity with which he has brought out these five volumes. They are to be followed by other series on practical surgery, on physiology, on midwifery, &c. The series already completed would be an excellent present for a young practitioner going to the colonies.

MEDICAL GAZETTE.

Friday, September 25, 1840.

ADVICE TO PUPILS.

FEW parts of our office are so agreeable as that of giving advice to pupils concerning the best method of studying the medical profession in London. We feel assured that, among the multitude who read our hints, there are many who will read them with profit ; while there is scarcely any class of persons so much in want of counsel.

The student fresh from the country, living in London with little superintendence, and disappearing, as it were, amid the throng of the greatest city in the world, is in danger of sinking into vulgar dissipation. Should his principles save him from this calamity, he may yield to the seductions of indolence, acquire mere fragments of information, and content himself with certificates instead of knowledge. Or, should he be of a higher stamp, he may fall into the more respectable mistake of studying the ancillary sciences to the exclusion of medicine itself, and thus becoming qualified rather to supply materials for the practical, than himself to practise.

We will, therefore, suppose a student just launched upon London, with no friends capable of supplying the counsel which he needs ; and while we touch upon a few points connected with his professional progress, however homely and prosaic some of them may seem, we trust that those who do not stand in need of the advice will not only excuse but praise us.

Among schools, it is safest to select one whose merits are attested by its duration, as well as by the general voice of the profession. At any rate, we would say to our young friend, avoid those schools whose attractions consist almost solely in the lowness of the fees. The frequency with which the lecturers are changed in such establishments shows that, happily, the system does not take ; and if such institutions spring up with alarming rapidity, it must be owned that they disappear fast enough also—" come like shadows, so depart."

It is desirable that the pupil's lodging should be near the hospital which he attends. This is especially necessary for the student who distrusts the intensity of his own industry, and who is conscious that he might be detained

from the scene of his labours, if distant, by bad weather, or other slight causes. For he must recollect, that if he wishes to learn the most difficult of arts, if he desires to practise physic as an honest man, the hospital must be the constant arena of his labours, as soon as his preliminary studies have qualified him to understand what he sees there. If he could find some fellow-lodger of the right stamp, a fellow-labourer for distinction, with whom to read, to reason, to dissect, to visit cases, his toil would be more delightful, and his progress more rapid; but such a chum is not found at the first call, and it is not a mere fellow-smoker that we recommend.

We sometimes hear of families where the master is a practitioner of physic, and is willing to receive students as boarders, and assist them in their medical studies. When such a port of refuge is to be found, not merely in a column of advertisements, but in absolute reality —when the head of the family is conspicuous for professional and moral character, while the readiness with which he acquires knowledge is to be surpassed only by the ardour with which he imparts it—the golden opportunity is not to be neglected.

We will suppose that the student intends to present himself at Apothecaries' Hall as a candidate for a license to practise. In this case, during his first winter session, he must attend lectures on four subjects, namely, chemistry, anatomy and physiology, anatomical demonstrations, materia medica and therapeutics. It would be highly desirable that the studies which the Court of Examiners have distributed over two years and a half should be extended through a longer period; especially when we consider that many students profess to attend at the same time the additional lectures required by the College of Surgeons. By the

last regulations of the College, indeed, the time of actual study has been extended to four years*, but it is not stated when the alteration takes place; but passing over this point, and supposing for a moment that the student is preparing himself for the Hall alone, he will attend three or four lectures a day. To this we must add reading and private study, without which lectures lose half their efficacy. The sum total might not be too much for a man of cultivated mind, habituated to severe study, and eager for a great object; but when we consider that too many pupils have passed their previous years of apprenticeship with so little profit, that they cannot explain the common terms of their art, nor recognize its tools when set before them, we must acknowledge that a potent struggle is required to conquer long habits of inactivity, and fertilize a fallow mind. But the struggle must be made, and every student who shrinks from the thought of defrauding the public of their money by homicidal practice, *will* make it. The first step is to observe the maxim *nulla dies sine lineâ;* let no day pass without some visible progress. Do not say " such or such a thing is so dry; I can't set about it to-day; tomorrow or Monday will do very well."

Incipe: vivendi recte qui prorogat horam,
Rusticus expectat dum defluat amnis; at ille
Labitur et labetur in omne volubilis ævum.

The great object of the diligent student, during his first session, will be to acquire a sound knowledge of anatomy. Haller says this requires twenty years; but we would not have our friend despair; he will find that the hearty efforts of six months, though they have

* Candidates are required to bring proof " of having been engaged in the acquirement of professional knowledge during a period of not less than four years, six months of which shall have been occupied in the study of practical pharmacy, six months by attendance on the practice of physic, and the remainder of the period on the practice of surgery, at a recognised hospital or hospitals in the United Kingdom: three months being allowed for a vacation in each year."

not brought him up to the standard of the German physiologist, have cleared away the first and greatest difficulties; and that the science on which he has toiled is " not harsh and crabbed, as dull fools suppose," but a perpetual fountain of knowledge and gratification. Though he will not formally dissect this session, he will probably have opportunities in the dissecting-room of trying his yet unskilled hand in the unravelment of the human frame. Nor do we see why he should not dissect a little this winter, though it may not count in his certificates. If not written on that folio sheet, it will be imprinted on his brain, and expressed in his conversation. It would be ludicrous, if it were not melancholy, to see the constant irrecognition of the simple truth, that these formal certificates are but one way of bearing witness to a man's studies; and that every one habitually testifies the amount of his own acquirements by his ordinary talk, as well as by his more elaborate essays. To make preparations is an admirable method of stamping anatomical facts upon the mind, while the result will afterwards revive recollections which time has begun to dim.

Materia medica and therapeutics form another great and interesting branch of study. We so lately touched upon the subject, when we directed attention to the prizes founded for its encouragement*, that we do not deem it necessary to dilate upon it now. We will only suggest that it would be well if pupils supplied themselves with specimens of the more important drugs, as a stimulus and assistance to their studies. Every one knows the difference between merely talking and reading about a subject, and actually having it before one's eyes.

Chemistry is one of the most delight-

ful of the sciences; and were the period of medical study considerably increased, might justly claim a large portion of attention. But the student who is absolutely limited to thirty months' attendance on lectures and hospitals, must stick to the practical with unremitting tenacity. He must master the elements of chemistry, but can hardly aspire to that apprenticeship in the laboratory which would form part of a complete medical education.

When attending lectures, the pupil will take short notes only, for the attempt to set down all that he hears, converts the auditor into a machine, and renders him unable to grasp the whole subject of an hour's discourse; but the notes should be written out at home more at length, and compared with the best authors on the same topics.

During the first summer session no attendance on lectures is absolutely required; botany, indeed, is mentioned, but the student may postpone it, if he pleases, to the second summer. We should advise him to take it during the first one, as the second will be better employed in recapitulating some of the more important subjects. We would not counsel this, however, if it obliges the student to remain in London; but if a recognized lecturer on botany is to be found near his habitual residence, we suppose it would be in accordance with the regulations to attend these lectures in the country; but on this point we speak with diffidence. If the case should be otherwise, it would be better to postpone botany to the second summer, when forensic medicine is to be studied.

During the first summer session, the pupil is recommended by the Court of Examiners to attend to " such other branches of study as may improve the student's general education." As they

---

recommend in their preliminary remarks that the pupil, previously to his apprenticeship, should "have received a sound classical education, have been instructed in the elements of mathematics, and natural philosophy, and have acquired a knowledge of the French, and, if possible, of the German language," they probably refer to these acquirements. Since the first vacation lasts five months (if botany is postponed) a good deal may be done in it; but as Apollo does not always bend his bow, neither should the medical student, and we must, therefore, allow a certain time for recreation. Hence it will perhaps be sufficient for the majority, if we suggest a considerable improvement in French and Latin as the fruits of their summer holidays. The latter accomplishment is so much neglected by students, that in one year, out of 106 rejections at the Hall, 36 were purely through ignorance of Latin*; not from the extreme severity of the examination, but from the remarkable incompetency of the candidates.

We will not, on the present occasion, comment on the studies of the remaining years, but we will conclude with a hint or two of a different kind. Let the young student beware alike of the riotous profligate, of the cold sneerer, and of the habitually discontented man; it is not from such that lessons of wisdom, or the art of happiness, are to be learned. Let him recollect that to cure disease is only a part of the general problem of mitigating pain; and that he whose temper and behaviour are a constant source of suffer-

to those around him, counteracts his own medical skill, and is but half a physician.

* MED. GAZ. Vol. xx. p. 696.

MEETING OF THE
NORTH OF ENGLAND MEDICAL
ASSOCIATION.

THE second general meeting of the North of England Medical Association was held at Carlisle on Tuesday, the 15th inst. Dr. Headlam, the president of the society, was in the chair. The topic of the day was medical reform. The proceeings were opened by a speech from the president; and this was followed by the Report of the Council, which was read by Mr. C. T. Carter, the Hon. Secretary. The meeting was next addressed by Dr. Barnes, Mr. Morrison, Sir John Fife, Dr. Knott, &c. Dr. Elliot then read a paper "On Scientific Medicine, and its Relations to, and claims upon Society at large."

Dr. Elliot's address is to be printed and published; and the annual subscription to the association is to be reduced from a pound to ten shillings, as the society now numbers 160 members. Thanks were voted to the president.

"The meeting," says the reporter in the Gateshead Observer, "was then dissolved, and several of the medical gentlemen present proceeded to the Bush Inn, where dinner had been provided for their entertainment. Dr. Headlam presided; and we need hardly say, that the short time which remained, prior to the starting of the 'train,' was pleasantly occupied. At 5 o'clock, the medical visitors of the 'merrie citie,' and the writer of this notice of the day's proceedings, were on 'the rail,' and swiftly journeying back to their 'canny' quarters in the east; and ere the evening was far advanced, they were snugly ensconced in their respective homes, and luxuriating over a comfortable cup of tea; having travelled 120 miles between nine in the morning and eight at night, and spent five hours out of the eleven in Carlisle."

ASSOCIATION OF PHYSICIANS, DUBLIN.

September 7, 1840.

The President, DR. COLLINS, *in the Chair.*

DR. LENDRICK read the following paper:—
There is always particular interest excited by those diseases that are attended by change of structure, and effects cognizable by the senses of sight and touch. Yet, as far as *medical* disease is concerned, this is precisely the class of maladies which, in general, are least amenable to treatment. It is therefore gratifying to come occasionally across cases that both present the strong

distinctive marks of organic disease, and also are capable of cure or alleviation.

Such was the one which I am now about to submit to the notice of the Association. A child, three years old, was admitted into Mercer's Hospital, and put under my care, on the 22d of June, labouring under palpitation of the heart and difficulty of breathing. On inquiry it was ascertained that about three months previously she had been thrown down by a carriage, two of the wheels of which had passed over her body. A medical gentleman, who witnessed the accident, directed a stimulating draught, for the purpose merely of producing revival. From the nature of the injury, and the amount of collapse, he did not anticipate her recovery. Obstinate vomiting ensued, and lasted a considerable time; but the other urgent symptoms of distress became mitigated.

About a month afterwards she was attacked with dyspnœa. Several local applications were used, and she was at length brought to my friend and colleague Mr. Read, by whom she was sent to Mercer's Hospital, and placed under my care. It was his opinion that the heart was displaced, and in this conclusion I fully concurred, the pulsation being obvious, both to the sight and touch, on the right side of the chest, and imperceptible on the left. Mr. Mason, one of our pupils, who afterwards paid great attention to the progress of the case, observed that the chest was much more prominent on the left than on the right side, and more accurate examination showed an increase of dimension of about an inch. The child was unable to lie on the left side without a sense of impending suffocation, and screamed on the attempt being made.

The sound, on making percussion over the left side of the chest, was completely obtuse. Some degree, of what seemed to be bronchial respiration, was audible at the upper and posterior part of the lung, and, as might have been expected, the sounds were remarkably distinct on the opposite side.

There could be no doubt as to the nature of the case, and that fluid was largely effused into the left pleura. It was questionable, however, whether the obvious change in the position of the heart was referable to the pleuritic effusion solely, or might be attributed partly to the thorax having been crushed by the injury, to which all the symptoms were traceable. The weight of the carriage, and the flexible state of the bones and cartilages at so early a period of life, in some degree countenanced this opinion.

The general want of success attendant on the operation of *paracentesis thoracis* deterred me from having recourse to it on the present occasion, and Mr. Read fully concurred with me in opinion. The treatment consisted of four grains of calomel and one grain of digitalis, administered in divided doses daily, and a blister dressed with one of Albespiene's papers, applied to the left side of the chest.

A few nights afterwards, a round worm, about seven inches long, was passed from the bowels. On the 2d of July the preternatural action of the heart was diminished; the pulsation seemed to be an inch nearer the centre of the sternum, and the difficulty of lying on the left side was diminished. The usual respiratory sounds now became discernible over the left side of the thorax.

About a week from the above date, the medicines were discontinued. At this time the heart had apparently resumed nearly its ordinary position; the usual sounds were heard over the chest; the morbid enlargement of the left side had disappeared, and the patient could lie with ease in any position.

On the 19th of July she left the hospital, seemingly quite recovered.

I have stated the facts of the case as they occurred. Of course, no importance can be attached to the evacuation of the worm, all the symptoms being obviously connected with a mechanical cause, the distension of the left pleura with fluid, and which seemed to be traceable to the injury inflicted by the carriage. Whether the displacement of the heart was solely dependent on the accumulation of fluid, or partly caused by the force of the injury, must be, as I have just remarked, doubtful. It would appear, however, that the pleuritic effusion was dependent on an inflammatory action, produced by the violence inflicted on the chest.

Under such circumstances the operation of tapping presents considerable inducements. The prompt removal of the fluid affords much temptation to having recourse to so simple a mode of effecting relief. I am, however, inclined to think that this very simplicity is an objection, and that when much sympathetic suffering is attendant upon the accumulation of a fluid, this circumstance ought to render us cautious of setting up in the constitution another disturbance, caused by the parts being made to assume suddenly the opposite state of vacuity. Inflammatory affections of serous cavities must for this reason be dealt very delicately with in the way of operation, which often substitutes an artificial state of disease worse than that under which the patient laboured. In the preceding case no attempt at an operation was made, and yet, under ordinary treatment, the symptoms subsided, the fluid disappeared, the heart regained its ordinary position, and recovery ensued.

Dr. Osborne produced two preparations of perforations connecting the œsophagus with the air-tubes of the lungs.

The first (of which a notice has already appeared in the *Dublin Medical Press)* was taken from a young man, who enjoyed good health till about four months previous to his death. At that time he was first observed to cough always after swallowing liquids. This increased so much that he was at length obliged to abstain entirely from drinking. On the morning of his death he was eating a breakfast of beefsteak, when he was seized with a fit of suffocation, and was brought to the hospital gasping for breath. A probang was passed with a view to remove the obstruction, but no improvement was obtained, and in a few minutes he died.

On examination after death nothing was found in the larynx or œsophagus to account for this sudden catastrophe, and the parts were on the point of being closed, when one of the assistants happening to put his finger down the œsophagus, felt something rough at the side of it, adjacent to the bifurcation of the trachea. This produced a further inquiry, and it was ascertained that a perforation had taken place exactly in the raphé above the bifurcation, that a portion of a piece of gristly beef had passed through it, which unfortunately for the patient had been divided into two portions, one of which had stopped up each of the bronchi, while it had been retained in its situation by a large portion connected with it, which remained in the œsophagus. The orifice through which it had passed was a longitudinal slit, which, when expanded, would form an opening equal to a fourpenny piece. There were no vestiges whatever of ulceration, or of any diseased process around the orifice ; and Dr. Osborne stated his opinion to be, that this was a case of congenital defect resembling cleft palate ; that owing to some accidental circumstance it had become enlarged four months ago ; when swallowing fluids was followed by a cough, and the irritation attendant on their escape into the bronchial tubes ; that the immediate cause of death was an irritation producing a necessity for coughing, unfortunately at the moment when the piece of beef had arrived opposite the orifice, when the unfortunate patient being obliged to make a sudden and forced inspiration preparatory to the cough, the beef was sucked into the trachea, and each lobe of it also sucked into a bronchial tube, which were thus as it were *corked up.* Perhaps there is not on record a more remarkable instance of loss of life from so singular a combination of circumstances : 1st, A perforation of the œsophagus penetrating the trachea just above the bifurcation ; 2dly, The patient making a forced inspiration just at the moment when a piece of meat was in the act of passing the perforation ; and 3rdly, The meat happening to be divided into three lobes, one stopping up each bronchial tube, while the third remained in the œsophagus, and thus maintained it in its position.

The second case was that of an individual who appeared to have possessed intellectual energies far above his station in life. He was a working shoemaker, and burthened with a family, but found time to combine the labours of authorship in various departments, with those of a political orator, and methodist preacher. About eleven months previous to his death he first experienced a difficulty in swallowing, which gradually became painful. When my patient was admitted into the hospital, he complained of lancinating pains in the œsophagus, even when not engaged in swallowing, which usually belong to the progress of scirrhous and cancerous disease in that part. The passage of the œsophagus tube, however, in the hands one of the ablest surgeons of this city, failed to detect any, even the slightest stricture. Under treatment the state of his stomach was much improved, but no improvement of deglutition obtained, and he went to the country. His condition did not become sensibly worse till about seven weeks before his death : then he was tormented with cough on every occasion of swallowing, or whenever he lay on the left side, and continued in this state of suffering till his death.

An opportunity of examining the body having been offered by the family, a very remarkable correspondence between the symptoms and the disease was brought to light. The greater part of the œsophagus was so much diseased that in the preparation it can scarcely be recognised. The ulcerations in several places formed large excavations in the mass of adjacent scirrhous structure. In the portion adjacent to the bronchial tube, a peculiarly large excavation has extended, engaging in it several of the bronchial glands, and here is an oval perforation with thin jagged edges, forming a direct communication between the œsophagus and air tube. The size of this being nearly one inch in length and half an inch in breadth, we can readily understand : 1st, How swallowing any thing solid or fluid produced coughing ; and 2dly, How some degree of ease was obtained by lying on the right side. It is also to be observed, that although both lungs were healthy, yet that at the apex of the left lung a collection of miliary tubercles were in progress of formation ; this being a result of the peculiar irritation to which that lung was exposed, analogous to the case described by Dupuytren, in which there were no tubercles in the body, except round a pin adherent in the lung.

Both those cases illustrate a lesion which has not been described in any work that has come into my hands, and which must be of great rarity, since no preparation of it is in the museum of the College of Surgeons, or in that of any other collection respecting which I have made inquiries. Perhaps, however, it has not been sufficiently sought for, and the communication of those cases to the Association may be useful, if it excites attention to the subject. As perforations between adjacent mucous membranes in other parts are not unfrequent—witness those between the vagina and rectum, the colon and stomach—this occurrence between tubes so closely adherent as the œsophagus, and air-tubes may be *à priori* expected to take place, and the above cases shewing that it actually does take place, it is to be inferred that the absence of observations of a similar kind has arisen from its having escaped observation, in consequence of pathologists having not sufficiently searched for it.

HÆMORRHAGE FROM THE CONJUNCTIVA.

To the Editor of the Medical Gazette.

SIR,

THE two cases of hæmorrhage from the conjunctiva, detailed in a recent number of the MEDICAL GAZETTE, by Mr. Hocken, of Exeter, are curious and interesting. They appear, however, fortunately to have been slight and easily suppressed. My too intimate with the records of medicine is they contain many such ..... to say whether in the course of my reading some years ago I observed one or two remarkable cases of bleeding from the eye, notes of which I will subjoin, and should you consider them deserving the notice of your readers, they are very much at your service. The first case in my note-book is from the works of *Forestus*. " Foresti opera omnia. fol. Frankfurt. an. 1634." Lib. ii. " De Morbis oculorum et palpebrarum."

Observatio xiii. " De Sanguine per tres fere Septimanas ex oculis lachrymarum instar copiose emanante et profluente."

" Lachrymas vero ab oculis profluere nihil novum est: at guttas sanguineas reddere, rarissimum : id tamen vidimus anno 1581, 23 Aprilis die, in vetula quadam annos 80 nata, quæ in parte orientali Delphio decumbebat, in domo cui flos calendulae pro insigni erat.

" Erat autem mulier procera et valde macilenta, cui et lachrymæ sanguineæ, imo sanguis, continuo fere per utrosque oculos fluxerant.

" Interrogavi quam diu hoc malo, nempe ictero laborasset, et sanguinem ex oculis profudisset ; respondit, tres septimanas elapsas esse, quibus hoc colore totum corpus infectum fuerat ; et statim ab eodem tempore satis continuo in hunc usque diem lachrymas sanguineas ex oculis emanasse referebat : Oculi tamen non dolebant, nisi quod mane ob sanguinem profusum difficulter aperirentur."

Forestus afterwards refers to a case given by Dodonæus, of a young girl aged 16, whose menses had not appeared, but in whom a vicarious discharge took place from the coats of the eyes :—" Sanguineis guttis lachrymarum instar frequenter ex oculis profluentibus."

The next case is from the Phil. Trans. No. 208, p. 51, An. 1694, being " part of a letter to Dr. Clopton Havers, F.R.S., giving an account of an extraordinary *hæmorhagia* at the glandula lachrymalis."

" Sir, since my coming to this place I have met with a very strange case. An icterical discontented woman having a desire to dye, wholly rejected the help of medicine, and within three months, being well nigh her end, there happened an eruption of blood out of the glandula lachrymalis of one of her eyes, without any external injury. There was an evacuation of lb. ii. of blood within the space of thirty hours. About a week after the same sluce was opened again, and she bled till she died. Now I would fain know what blood-vessels come to that gland from which such a vast quantity of blood should be cast forth in so short a time." —I remain, sir,

Your obedient servant,

LECTOR.

CHARLES HENRY ADAMS.

NOTICE.

We have received the communications of Dr. Franz, Mr. J. I. Adams, Mr. Hugh Carmichael, Mr. J. B. Gray, and Dr. Murphy. We are much obliged to Mr. T. C. Cartner for his attention.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By DR. WATSON.

LECTURE II.

Pathology — meaning of the term. Pathology, general and special. Morbid alterations of the solid parts of the body. Alterations in bulk. Hypertrophy, — law of its production — its effects. Atrophy — its causes and consequences. Changes in form. Alterations in consistence. Induration — its various kinds.

I PROPOSE to devote several lectures, in the commencement of the course, to pathology, as it relates to medicine.

And I must first of all explain to you what I mean by the word pathology.

Many persons speak of pathology as if it were the same thing with morbid anatomy. That is not the sense in which I purpose to use the term. Pathology *is* morbid anatomy, but it is something more.

A knowledge of pathology (in the full and proper acceptation of the word) implies indeed a knowledge of altered structures and of diseased conditions ;—but it implies also an explanation of these — a knowledge of what precedes them, and a knowledge of what results from them.

It comprehends therefore the following particulars : — 1. A knowledge of the material changes to which the several parts of the living body are subject : 2. A knowledge of the proce-ses or actions by which these changes may be wrought : 3. A knowledge of the causes which set these processes on foot ; and 4. A knowledge of the consequences of the same changes, or of the symptoms they occasion.

670.—XXVII.

On some of these points our actual knowledge is still scanty and imperfect. Yet a good deal of valuable information concerning each of them has been collected : and this I shall endeavour to place before you as distinctly, and at the same time in as small a compass, as I can.

Pathology is general, or special. General pathology treats of the morbid conditions which are common to the whole system, or to the several tissues that compose the system. Special pathology contemplates particular diseases. An acquaintance with general pathology prepares us for, and conducts to, that which is special ; and when I say that the earlier lectures of the course will be given to a consideration of the facts and doctrines of pathology, you will of course understand me to speak of *general* pathology.

And I shall begin by inquiring what are the changes to which the component parts of the living frame are liable.

There are various ways, capable of intelligible description, in which the different parts of the body may be altered by disease.

The solid parts may be altered in *bulk ;* in *form;* in *consistence;* in *their intimate texture,* i.e. in the qualities and arrangement of their component particles ; and in *situation.*

The fluid parts may also be altered in *quantity ;* in *quality ;* and in *place.*

And many of these alterations may exist in combination with each other.

Let us first consider the solids.

They may be simply altered in bulk without any change of texture ; and that in two ways. They may become larger than natural, or smaller than natural. In the one case the change is called *hypertrophy,* in the other *atrophy.*

Hypertrophy.—We find the best illustrations of hypertrophy in the muscular system. The huge muscles visibly prominent in the arm of a blacksmith or pugilist, and in the leg of an opera dancer, afford familiar ex-

D

amples of it. In these cases the increased bulk, although it may be unsightly, as being out of proportion to other parts, is not disease, and does not interfere with the most perfect health. By constant exercise the muscles acquire preternatural volume, and weight, and power. It seems to be a law which prevails extensively in the animal economy, that increase of function should lead to augmentation of bulk. The function of the muscular system is contraction, and more frequent and energetic contraction begets an addition of substance. But the same principle obtains in various other parts and tissues. It is especially noticeable in some of the organs which are double. If one kidney wastes, or is spoiled by disease, an increase of function is thrown upon the other, and by a beautiful law of compensation, the sound organ, without any alteration of its peculiar fabric, enlarges. The same is observed to be the case with the lungs. The law resembles, somewhat, one that is familiar to political economists, and is expressed by them in the maxim — that the supply of a marketable commodity is regulated by the demand for it. If, in respect to a muscle, increase of force be habitually needed, the necessity generates the requisite addition of bulk, which implies an augmentation of force. One kidney becoming inefficient, it is necessary the other should secrete a larger quantity of urine; and this faculty is obtained by the enlargement of the secreting organ.

I say this law is of extensive operation in the living body : but it is not universal. It does not hold, for instance, in respect to the organs of the special senses. One eye does not become hypertrophic when the other is blind ; nor one ear grow larger or longer because the other is deaf. And we see at once why the law in question does not apply in such cases. These organs differ from such as I mentioned before—from muscular and glandular parts—in this ; that increase of their size would not augment or facilitate the function or purpose they are designed to serve. A muscular arm will strike a harder blow, or lift a heavier weight, in proportion to the bulk of its muscles : but we should gain nothing in distance or distinctness of vision by the enlargement of an eye ; nor should we hear more acutely or more clearly if our ears were of twice the ordinary magnitude.

Hypertrophy of this unmixed kind — unattended by any change of texture—(and it is to this that the term should as much as possible be restricted) is believed to depend upon more active nutrition of the part. ($\upsilon\pi\epsilon\rho \tau\rho\text{o}\phi\eta$). More materials are laid down in the part by the blood, and assimilated, than are received back from the part into the blood to be taken out of the body.

The nutritive process preponderates over the reabsorbent. That hypertrophy does thus result from an excess in the process by which parts are nourished and built up, and not from a defect in the process by which they are decomposed and removed, is rendered probable by the fact that an increased quantity of nutrient blood is sent to the hypertrophied part ; its arteries grow larger : this we perceive by comparing these vessels with others where no accession of bulk has occurred. This opinion is further strengthened by the converse effect produced upon an hypertrophied part (the thyroïd gland, for instance) by tying its principal nutrient artery. The magnitude of the bronchocele diminishes. It is curious that no such alteration of size has been noticed in the nerves supplying the hypertrophied parts.

Now these examples of hypertrophy clearly have not the nature of disease. But hypertrophy is often plainly connected with disease, while still it is not itself a morbid process. Thus we have it in the hollow contractile organs, the office of which is to propel fluids : — in the heart when the progress of the blood suffers some mechanical obstacle ; in the bladder when the urine, and in the intestinal canal when its contents, are somehow hindered in their natural course ; or when, from some undue stimulus or irritation, these parts respectively are urged for a long time together to excessive, or too frequent, action. I shew you preserved specimens of each of these changes. You will find that muscular structure sometimes becomes apparent, under the influence of disease, where very slight traces of it, or none at all, were visible before. You may sometimes observe this in the air tubes, the trachea and bronchi, when the respiratory functions have been long embarrassed ; and in the gall bladder, when the exit of the bile has been chronically impeded. And it is worth remarking that this new, or greatly exaggerated appearance of muscular tissue, which is the product of disease in the human body, is a part of the natural and healthy structure in some of the inferior animals.

The several instances of hypertrophy that I have now been mentioning, if they are to be looked upon as morbid, are morbid in a particular and limited sense—morbid, merely as being associated with disease, and not so either in their own processes or in their tendencies. Many indeed of the writers who notice them, speak of the hypertrophy as constituting a source of disease, and a cause of danger to the patient. But I shall have occasion to shew you hereafter that in most cases it is really a compensatory change, and conservative of life ; —a resource of nature by which impending danger is postponed, and existence prolonged.

It may be said of hypertrophy, that it has to do with disease or not, very much according to its seat. As regards the muscular system—in the voluntary muscles it is generally innocent, in the involuntary it is generally connected with disease, sometimes as a cause, much oftener as a consequence, sometimes as both cause and consequence. One way in which hypertrophy may manifestly be a cause of disease is by the pressure of an enlarged organ upon the parts in its neighbourhood, and a consequent interference with the functions or the sensations of those parts.

I am not sure, whether, to those among you who are beginners, I make myself understood. An example or two will render what I mean obvious.

It often happens that the aortic orifice of the left ventricle of the heart becomes narrow and constricted, in consequence of disease in the semilunar valves there situate. Under these circumstances, more forcible contractions of that ventricle are required for the due propulsion of the obstructed blood, and the walls of the ventricle become, accordingly, thicker and stronger. Here the hypertrophy of the left chamber is evidently a consequence or *effect* of the disease that previously existed at its outlet.

On the other hand, when the thyreoid gland is enlarged, it sometimes presses so much on the parts that lie behind it, as to impede the breathing, or the swallowing. In this case the hypertrophy is the *cause* of consecutive disease.

Hypertrophy is exceedingly common in other tissues as well as in the muscular. Of its affecting the glandular system we have good examples in what I have just mentioned, the true bronchocele — in certain forms of enlarged prostate — in the thymus gland not unfrequently. Hypertrophy of the adipous tissue displays itself in partial accumulations of fat—or in that general and extreme obesity which may amount to disease, and which nosologists have called *polysarcia*. Of a state of the brain which is considered to constitute hypertrophy, I shall speak more particularly when we come to the morbid conditions of that organ. Hypertrophy is also said (I am not certain with how much propriety always) to occur in the cutaneous, mucous, and vascular systems, in the bronchial, mesenteric, and mammary glands, in the liver, spleen, and pancreas. I suspect that the enlargements of these parts to which the term hypertrophy has been sometimes applied, most frequently combine some alteration of texture with the increase of size, and therefore are not strict examples of hypertrophy.

It is of importance that you should be aware that hypertrophy of one or more of the component tissues of an organ may

exist, while the others either remain unaltered, or are changed in some other way. It frequently happens that when one component part is thus over nourished, it is so at the expense (as it would seem) of another which becomes atrophied. There are parts of the heart upon which a certain quantity of fat is usually deposited. It is not uncommon to meet with this in excess, and at the same time to find the muscular texture of that organ pale, flabby, soft, and wasted. What has been deemed hypertrophy of the female breast consists, almost always I believe, in excessive development of its adipous tissue, without any enlargement of the gland itself – or even with its diminution.

In the majority of cases the size of an hypertrophied organ is augmented; it has a larger superficies than is natural: and, therefore, I have introduced hypertrophy to your notice among the alterations to which parts are liable in *bulk*.

But it is not always so. There may be hypertrophy of an organ without enlargement—in at least three different ways :—

1st, In hollow organs, where the additional substance is deposited centrally, and the hypertrophy takes place at the expense of the cavity :

2dly, In any organ, whereof the hypertrophy is confined to one or more tissues, while the others are proportionably wasted: and,

3dly, Hypertrophy may even be consistent with no alteration of shape, or increase of bulk in any direction, the organ occupying exactly the same space, and preserving the same absolute dimensions as before, but becoming more full of component particles, more compact, heavier. This state is well exemplified in certain cases of hypertrophy of bone : the spongy or cancellous texture of the bone disappears—its specific gravity is increased—it becomes hard, firm, and like ivory. The structure appears, to the eye, to be changed, yet remains the same, except in respect of its density.

I have told you that hypertrophy is usually a conservative and salutary change. We shall meet with many illustrations of this as we proceed. But I may take the present occasion of pointing out to you some of the beneficial tendencies of this change when it takes place in bone. For, since the diseases of the bones do not belong to my province, I shall have no other opportunity.

You probably know that in the disorder called rickets, occurring principally in childhood, the bones are soft, and deficient in their more solid ingredient ; so that they bend under the weight of the body or the contraction of the muscles attached to them : after a certain period this disproportion in the constituent particles of the osseous tissue ceases ; but the bones are permanently

distorted, and, therefore, less adapted to their office, and less strong, than if they had remained straight. Now the natural remedy that ensues is very striking and beautiful. The bent bones become *hypertrophied* in certain places ; they grow thicker, denser, harder, and, consequently, stronger, at the very concave part where the stress of the pressure is the greatest.

The following experiment shewed the same thing in a somewhat different manner. An inch of the middle part of the fibula of a quadruped was cut out. A long time afterwards the animal was killed. The tibia was then found to have become considerably thickened exactly in that part of it which corresponded to the defect in the fibula*.

The same principle appears still more conspicuously in a case of disease related by Cruveilhier. He saw in the Hospital at Limoges a young man who had lost, (from necrosis with suppuration) the middle third of his tibia; of the larger of the two bones of the leg. The lost bone had not been reproduced, but the fibula, the naturally slender bone, had become thick and strong enough to support the whole weight of his body.

I was explaining to you that hypertrophy may exist, without enlargement. On the other hand there may be enlargement, without any change of structure, and yet no hypertrophy. The liver and spleen are apt to acquire a considerable increase of bulk from mere congestion and distension of their vessels by blood. An immense spleen will shrink into its proper size in a few hours, after hæmorrhage from the stomach, whereby the gorged venous system of the abdomen has been relieved. Dr. Townsend mentions a remarkable example of the same kind respecting the liver. The inferior cava had been compressed by an aneurismal tumor, so that the passage of blood from the liver was greatly impeded. Under these circumstances the liver became so large as nearly to reach the crest of the ilium. Suddenly the aneurism burst, the pressure was taken from the cava, the hepatic veins were allowed to empty themselves, and before the body was opened for inspection, the liver had nearly resumed its natural situation and dimensions.

Of the causes of hypertrophy little more is known than I have already told you. The most important circumstance for you to remember is that increase of function produces increase of nutrition. This is nearly a general fact; but whether the converse proposition be as generally true — whether hypertrophy of a part always denote increased activity in its function—is much less certain.

If that were ascertained, we might hope to discover the actual office of certain parts of the body, the uses of which we do not yet understand (of the thyreoid gland, for example) by investigating the circumstances under which they become subject to hypertrophy. In Mr. Mayo's *Outlines of Human Pathology*, a case is related of hypertrophy of the tongue, in a young child, treated by Mr. Hodgson, of Birmingham. It would seem to be impossible to account for this by any increased energy in the known functions of that member.

A few isolated facts, bearing upon some points connected with this inquiry, have been made out.

In the first place, certain localities appear to be influential in the production of certain forms of hypertrophy. Thus bronchocele is very frequent among the inhabitants of certain districts — especially in close or marshy vallies at the feet of high mountains. Its real cause is to be sought in some condition, hitherto undetermined, of the air of those places, or of the water, or of both.

2dly. Certain congenital or acquired conditions of the body tend to produce local hypertrophy. In that peculiar diathesis which we call the strumous—and of which I shall have much to say hereafter—certain parts of the body, as the upper lip, and the extremities of the long bones, undergo a kind and degree of enlargement that seems properly to fall within the definition of hypertrophy.

3dly, Certain habits of life have a distinct effect in promoting certain forms of hypertrophy. Full diet, with bodily inactivity, leads to hypertrophy of the adipose tissue. So general is this tendency, that we confidently act upon it in the fattening of animals. Shut a healthy pig up in a small sty, and give him as much food as he is willing to eat, and you ensure his rapid pinguescence. If you cannot so certainly attain the same result by similar means in the human animal, it is chiefly, I believe, because moral causes, and especially mental anxiety, will effectually counteract those means. A healthy man, with a quiet mind, using habitually a full nutritious diet, and leading a sedentary life, will fatten, I apprehend, as unfailingly as a calf, or a turkey. Sometimes, indeed, fat accumulates, to an enormous extent, in spite of abstinent habits, and very active exercise.

4thly, It is a curious fact that the removal of certain parts of the body, as the testicles in male animals, and the ovaries in females, increases the disposition to accumulate fat. The same tendency appears to be given, for a time, by the extirpation of the spleen.

Of the curative methods that hypertrophy may require it would be premature to speak at present.

---

* Mr. Stanley's Lectures, Coll. Surg.

The *bulk* of parts may also be *augmented* in various other ways. The hollow organs may be inordinately distended by an undue accumulation of their natural contents,— or by matters that do not enter them in health :—the solid organs may have their size increased by the presence of matter foreign to their natural composition, collected in their interior, or distributed through the interstices of their proper tissues, or deposited upon their surface : and in each case the functions of the part itself may be disturbed or suspended ; or the functions of parts immediately contiguous to it may sustain damage from its pressure ; or the functions of distant parts connected with it by dependency of office may be disordered ; or all these consequences may exist together. Numerous examples of them all will hereafter be brought under your notice.

Atrophy.—Let us next attend to that condition which is the opposite of hypertrophy—to *atrophy*, namely, in which parts become notably smaller than natural, without other alteration of texture.

The two conditions contrast strongly with each other in their nature and origin, as well as in their physical character.

Hypertrophy depends essentially upon an increase — atrophy upon a diminution or defect, of the nutritive functions. You will find that atrophy plays an important part in altering the bodily organs, both in health and in disease.

Of the effect of atrophy in causing alterations consistent with health, I shall merely remind you of some instances, that you may the better comprehend its morbid operation.

There are parts of the body, as you well know, destined for a temporary purpose only. Upon the cessation of their especial function they dwindle, or disappear. We have examples of this in the thymus gland, in the supra-renal capsules, and in those parts of the mechanism of the circulation that are peculiar to the foetal state. The atrophy here begins as soon as the child is born, and not only is consistent with, but is necessary to, its perfect health. As life advances, we see the same principle at work, remodelling from time to time those structures of which the office has only a limited duration. After the child-bearing period in women is over, when the functions of the ovaries expire, these organs shrink, through atrophy. It is so with the testes of old men. Indeed atrophy, to a certain extent, pervades all parts of the system in old age : the muscles diminish in size, the whole body is less plump, the bones lose a portion of their substance, and become brittle.

Even in the period of foetal life this process, by which parts are starved and stunted, sometimes displays itself. But here it is no longer compatible with the integrity and well-being of the system. The arrest or retardation of the nutritive function produces changes of great interest, and gives rise to various kinds of monstrosity. Harelip— fissure of the palate—certain malformations of the heart—are familiar examples of the consequences of intra-uterine atrophy.

Atrophy, considered as a morbid process, is conspicuous, no less than hypertrophy, in the muscular system. We see it in the voluntary muscles, whenever a limb remains long in a state of inaction – whether from palsy dependent upon disease in the brain or spinal cord ; or from pain connected with disease of a joint ; or from perversion of the will, as in the self-inflicted penance of the Fakir. The same law, therefore, obtains here, which was previously announced ; the development of a part is proportioned to the activity of its function. In most cases I believe the atrophy will be found to resolve itself into a deficient supply of healthy arterial blood. Mere inaction will produce it ; but it is probable that the inaction operates simply by diminishing the flow of arterial blood to the muscle. It has, indeed, been supposed that in paralysed limbs the altered condition of the nervous influence has also some share in determining the atrophy. The alleged facts on which this supposition is founded are of this kind. In the first place, when the palsy is imperfect, the diminution of bulk in the muscles is not always (they say) in proportion to the degree in which their power of action is impaired. But it is not very easy to measure and compare, in different cases, either the amount of action remaining to the muscles, or the degree in which they waste. Secondly, it has been remarked that when a limb is deprived of the power of motion by some injury that destroys or interrupts the functions of its principal nerve, atrophy takes place to a greater degree, and more rapidly, than when the palsy results from disease of the brain. But any local injury which affects the functions of the nerve will be likely to impair the functions of other parts of the limb also, and among the rest, those of the arteries. I therefore look upon the proposition, that what is called a "*change in the innervation*" of a part tends to occasion its atrophy, as at least a questionable proposition : and even if its truth could be established, the change of innervation would be most likely to operate by somehow reducing the supply of healthy arterial blood. The nerves belonging to palsied and atrophied muscles are said not to diminish in size. It is with the arterial circulation, certainly, that atrophy is most concerned. It is upon a diminution of the

number of the smaller, and, perhaps, also of the capacity of the larger arteries, that senile atrophy depends. We find atrophy of the brain accompanying certain diseased conditions of its main arteries. So the testicle withers when the spermatic artery is tied for the cure of varicocele.

Pressure of any kind, exercised either upon the larger arterial trunks, or upon the capillary vessels, so as to lessen without completely preventing the supply of blood, will be found to give rise to atrophy, whenever the due quantity of blood is not furnished by the establishment of a collateral circulation. *Chronic inflammation* is sometimes attended by the wasting of the part which it occupies. It acts, in all probability, by unfitting the capillary arteries for transmitting the requisite quantity of blood. Various diseases, by which the supply of nutriment to all parts of the body is checked at its source in the digestive organs, or by which some unnatural drain upon the system is kept up—by which, in short, the quantity of the nutrient fluid is diminished, or its quality impaired—produce a greater or less degree of *general* atrophy : but to this universal wasting we usually apply the term *emaciation.*

Atrophy, then, such at least as is morbid in its nature, may be the consequence of inaction, of compression, of chronic inflammation, and of various diseases : but in all cases the defect of nutrition which causes the atrophy seems to be resolvable into a diminished supply of healthy blood through the arteries.

As in hypertrophy, so likewise in atrophy, the change may be limited to some one or more of the component tissues of a part :— and from this altered proportion of its constituent tissues the appearance of the part may be remarkably modified.

So also, as hypertrophy may exist without any increase of absolute size, atrophy may occur without any diminution : as in the heart, when the cavities are dilated in the exact degree in which their walls become thinner. Bones, externally sound in appearance, have had their specific gravity so greatly reduced by internal atrophy, that they would float upon water like a cork.

It is a curious fact—which I mentioned in other terms before,—that an atrophied part is sometimes plentifully encompassed by fat. But this is by no means a necessary accompaniment. Why it happens in one case, and not in another—whether the adipous hypertrophy is ever the cause of the atrophy associated with it, or the atrophy the cause of the hypertrophy :— these are questions which, in the present state of the science of medicine, do not admit of any certain solution.

It is scarcely necessary to observe that the changes of *bulk* which we have been considering, imply often, though not always, changes of *form* also. You will have one or two of the chambers of the heart greatly enlarged, while the others remain of their natural size. Of course this altered proportion modifies the shape of the organ.

Signal changes of form are produced also by inflammation, by pressure, and in various other ways. But after all, modifications of figure are rather to be considered as *accidents* of disease than among its important *elements :* and I pass on to other alterations.

Induration.—Various parts of the body are liable to be changed in *consistence.* They may become harder and firmer than before : or they may become softer.   To the state of increased or unnatural hardness the term *induration* has been applied : the same word is used also to express the process of hardening. To the state of diminished consistence we give the name of *softening.* The French pathologists, who first noticed this condition as an element of disease, call it *ramollissement.*

You are already aware—those of you who have attended the lectures of the Professors of midwifery and of anatomy—that a slow process of natural and healthy induration is going on throughout the body from the earliest period of uterine life to extreme old age.

There are several ways in which *unnatural* induration may take place.

Induration of an organ may happen, without any other alteration of its proper tissue, in consequence of inordinate fulness of its blood-vessels. This is apt to occur in the lungs, or liver, whenever the free exit of blood from these organs is in any way impeded. They become stretched, tense, resisting, hard.

In like manner induration of the hollow organs, or of cellular parts, will arise (without any change of their texture) from an undue accumulation of fluids within them :— of bile, for example, in the gall-bladder—of urine, in its receptacle — of gases in the stomach and intestines—of serosity in the cellular tissue.

In either of these kinds of induration the unnatural hardness may be temporary only— or it may be the permanent accompaniment of other disease. It is necessary that you should be aware of its occurrence, and of its nature. I say of its *nature*, because this is not always understood. In the induration arising from the last circumstance I mentioned—viz., from infiltration of the cellular tissue with the serous or albuminous parts of the blood—from *œdema*, in short—the hardness has sometimes been erroneously ascribed to some other morbid condition.

Dr. Carswell has shewn that in the curious disease of new-born children who are said to be *skin-bound*, the hardness of the surface is the consequence of simple œdema of the subcutaneous cellular tissue. The same phenomenon is remarkable in œdema of the tongue. I believe the induration belonging to œdema will be found to be the greater in proportion as the effusion is recent, and has taken place rapidly.

Again, induration may accompany, and be a consequence of, simple hypertrophy. Of this I have already shown you examples: especially in the eburnation (as it has been called) of hypertrophied bone.

Induration of an organ may also result from the *ex*pression of its fluid, and the *com*pression of its solid parts. We see this extremely well in the lung, when it has been thrust and flattened against the vertebral column by fluid effused into the pleura — or when it is still more tightly bound down by an investing layer of plastic lymph. In this way, therefore, induration may be consistent with atrophy. That the natural structure of the hardened lung is not always lost in these cases we know, because we can restore, to a certain extent at least, its bulk and spongy feel, by forcibly inflating it. The spleen sometimes exhibits the same kind of induration, under the constricting force of an investing false membrane. I am mentioning samples only of these changes.

More frequently induration depends upon the presence, in the internal texture of parts, in the little spaces left between their component tissues, of fluid or solid matters which are not found there in the healthy state. Bony or earthy particles are sometimes laid down, and the part thus changed is said to be ossified. There are few parts of the body in which this kind of induration does not occasionally take place. It is especially common in the coats of arteries, and in the subserous tissues. Blood, or fluids separated from the blood, may fill and obliterate the natural interstices, and concreting, tend to solidify and harden the part which they occupy. What is called *hepatisation of the lung* is a good instance. I need not tell you that the healthy lung is spongy and crepitant under pressure: in this altered state it no longer crackles between the fingers—its spongy character is lost — it resembles liver in its compactness and colour, and it is therefore said to be "hepatised." This is a consequence of inflammation; and induration of this kind is a very common consequence (as we shall see) of the same morbid process in various other parts and organs. Another instance of induration of the pulmonary substance we have in what is badly called pulmonary apoplexy. This is inde-

pendent of inflammation. Blood is collected and coagulates in a part of the lung which should contain air—in the vesicles of one or more of its lobules: the lobules thus gorged with blood become even harder and firmer than when hepatized—but by a different process.

In the instances last mentioned, fluids, after escaping from their proper vessels—*i.e.* in technical phrase, after being *extravasated*, pass into the solid form, and thereby render the parts which they pervade harder and more firm. But fluids may concrete and harden *within* their proper vessels, and so lead to another form of induration. Thus the blood, under certain circumstances, coagulates in the living veins—nay, sometimes even in the heart itself: and we may hereafter have to consider the conditions under which this coagulation is liable to occur, and the serious consequences that it involves. The bile again, as you probably know, sometimes concretes, by a rude kind of crystallisation, into what are called gall *stones:* and the passage of these calculi through the narrow ducts that connect the gall bladder with the bowel is apt to be attended with pain the most intense. The formation of *urinary* calculi is not exactly of the same kind.

Numerous specimens of all the changes I have been describing are upon the table before you. You may examine them at leisure after lecture, or in the museum.

I have yet to notice another source of unnatural induration, in the deposition or growth of unorganised masses of matter within the body, differing remarkably from any of the solids or fluids that enter into its healthy composition. These unnatural formations vary considerably in their nature and appearance, and in their consistence at different periods. Sometimes they exist in distinct and separate masses, and whether hard or soft in themselves, cause induration by their pressure upon surrounding textures: sometimes they are diffused through or among the natural tissues of a part, which thus they indurate. All the varieties of tubercle, and of carcinoma, and many other forms of disease which have been styled malignant, fall under this head.

These new and morbid products play a fearful part in disorganising the bodily frame, and in embittering and shortening life. They will necessarily occupy much of our attention in the progress of the course. At present I merely point them out as illustrations of the manner in which the consistence of parts may be *increased*.

A RÉSUMÉ OF
DR. FRANZ'S EXPERIENCE IN CURING STRABISMUS

BY AN OPERATION; BEING AN ANSWER TO THE NOTE, IN A LATE NUMBER, SIGNED "SOLOMON SINGLE-EYE."

To the Editor of the Medical Gazette.

SIR,

As I have had the opportunity of judging of the ultimate effects of Dieffenbach's operation for strabismus, I beg leave to state in general the result of my experience, for the express satisfaction of the inquirer regarding squint-curing, being an answer to the questions contained in his note published in your number for Sept. 19.

I will, in the first place, mention a few points on which the perfect success of the operation depends. If these points are not adhered to, certainly the squinting may not only not be cured, but rendered even more formidable, or sight, if not the organ itself, entirely be destroyed.

Istly. Not every case of squinting admits of treatment by operation; great care and attention must be paid, therefore, to the selection of the case. The muscles drawing the eye out of position, the division of which is intended, must actually be shortened or contracted. The contraction of the muscles is either congenital or has become habitual. The cause of this habitual contraction, whatever it may have been, must by therapeutical or surgical means have been removed, so that its action at the time of operation no longer exists; or it must be of such a nature that we may reckon upon eradicating it entirely in time. The squinting must not be complicated with malformation or organic disease of the brain, of the orbit, or the parts in the orbit. The age of the patient is also to be taken into consideration. In my opinion, the success of the operation will be very doubtful (with the exception of a few cases) where squinting has existed from forty-five to fifty years.

2dly. The operation must be performed with care and skill. The ball of the eye itself must never be injured. The conjunctiva of the canthus towards which the eye is turned must be more or less separated from its connections with the globe. The shortened muscles must be perfectly divided, either in their tendinous portion close to the sclerotica, or in their muscular fibres at a greater distance from this membrane, or, what amounts to the same thing, all connections of the shortened muscles with the sclerotica must be more or less separated. The degree of squinting determines the extent of separation of the conjunctiva, as well as of the muscles from the ball.

3dly. Even if these two principal rules have been thoroughly observed, the result may be yet unsuccessful, where the after-treatment is not properly conducted. An appropriate use or exercise of the eye, and strict attention to the activity of the antagonizing muscle, are here the chief indications.

Where these three principles are strictly adhered to, a perfect and permanent cure of strabismus may always be predicted. The perfect success of the operation consists not only in the removal of the unsightly deformity, but in the pupil occupying exactly the centre of the orbit; in the eye enjoying freedom of motion in harmony with its fellow, together with an expressive look; in its restoration to perfect vision, which, during the existence of squinting, was very limited; and lastly, in the patient operated on feeling himself removed from the sphere of popular prejudice, and restored to that tranquillity of mind of which he, in common with all deformed persons, was deprived.

I have now performed this operation in fifty-three cases. In all the squinting was convergent, and in a few the eye was at the same time directed inwards and upwards. In most cases the squinting existed but in one eye; in many it was combined with a cast in the other. In two cases the inversion existed in both eyes to such an extent, that a large portion of the cornea was hidden by the inner canthus. In eight cases the deformity was congenital; in eleven it had arisen from imitative instinct. In five children partial opacity of the cornea was combined with squinting, which was treated before the operation was undertaken. One case was first operated upon for a partial symblepharon; two cases for cataract. In one case the eye was not only atro-

phied, but totally amaurotic. In another patient the remote cause of squinting was an earlier hydrocephalus; the proximate, a debility of the abductors of the eyes, which also occurred as a complication in many of the other cases. In the rest of the cases of habitual squinting, it had its origin in various ophthalmias, teething, convulsions, injuries, &c. In all the affected eyes weakness of sight existed to a greater or less extent; many of them were perfectly myopic. Muscæ volitantes, photopsia, nystaxis or nictitatio palpebrarum, occurred in a few cases. Where the eye was much inverted, the pupil was observed to be dilated when the eye was in this state.

As regards the steps of the operation, the fixing of the eyelids was generally effected by the fingers of one assistant, to save the patient from the great and unnecessary pain which the retractors always cause. The ball of the eye was always kept in position by a fine hook passed through the conjunctiva, or by a pair of forceps adapted for this purpose, in order to spare the globe from all dangerous pressure and wounds, which the double hook for the sclerotica imparts to it. A blunt hook for passing under the muscle was never found necessary; but it may be of service after the completion of the operation, if used as a probe to ascertain that all the fibres of the muscle are thoroughly and perfectly divided. In nearly all cases the conjunctiva was divided with a pair of scissors; and in all these were used for the division of the muscle. The muscle was found atrophied in but few instances; in some it was hypertrophied, and in many its attachments were irregular, bundles of muscular fibres being inserted to the sclerotica behind the proper tendon, or this expanded to a greater or less extent upwards or downwards. The bleeding is always inconsiderable, generally amounting to but few drops. The operation is simple, causes but little pain, and may, where the patient is quiet, be performed in one minute. In not one case was the operation followed by inflammation. In five cases it was necessary to divide, besides the internal rectus, the superior oblique also; and in some to divide partially the superior or inferior rectus. In one case where, after division of the adductor, the abductor drew the eyeball to too great a degree outwards, and kept it in that position, the external rectus was divided a fortnight after the first operation.

The pupil occupied its normal position in most cases immediately after the operation: in some it was first directed a little outwards, or was not on a level with the pupil of the other eye, but in both instances righted itself within the first four or eight days. In a few cases where the pupil occupied its proper position immediately after the operation, it became slightly inverted a week afterwards, but regained its normal position in a space of from four to six weeks, by proper exercise of the eye. In three cases the pupil of the operated eye is yet slightly inverted, but even then only when the persons look at objects near them. This may be attributed to the squinting, which was very marked, having been of 16, 23, and 44 years' standing in these respective cases, besides being complicated with a considerable degree of amblyopy, short-sightedness, and weakness of the external rectus. Neglect of proper exercise of the eye in the one case, in the other a catarrhal inflammation, which attacked the eye a week after the operation, greatly contributed to this result, that may yet in time be remedied by judicious exercise of the eye, and the treatment of the weakness of the external rectus, which is still continued. In the third case the use of caustic, which was three times employed to destroy a tumescence of the conjunctiva, seems to have contracted this membrane, and have caused the slight cast yet to be observed. The above-mentioned case, where the inversion had originated in hydrocephalus, presents also some peculiarities. After division of the shortened muscles, the squinting yet remained almost in the same degree as before the operation. By a proper exercise of the eye, by treatment of the almost paralytic state of the abductors, and by a second division of the adductor in the one eye, I however succeeded in bringing both eyes into a perfectly normal condition.

The wound in the conjunctiva generally heals in a few days. Where this membrane does not unite perfectly with the sclerotica, it assumes the appearance of an excrescence, which may be more safely and more readily removed with the scissors than by means of

caustic, thus sparing the patient also a great deal of pain. A cicatrix never remains in the conjunctiva; the redness of this membrane in the canthus also disappears within two or four weeks. In some few of my earlier cases the valvula semilunaris, which had been injured, is not yet quite regenerated, and the ball appears a little more prominent. Those eyes that were slightly affected with weakness of sight, regained in a few weeks a full power of vision; but where amblyopy existed to a greater degree, this improvement of sight did not take place until a longer time had elapsed, and in some even therapeutical means were necessary. Many saw objects situated towards the temporal side of the operated eye more distinctly than those in other situations. In all, double vision of objects situated towards the nasal side was remarked: in some this occurred immediately after the operation, in others after the lapse of a week or more. Some few saw objects double only when placed in a particular position. This distinctness of vision towards the temporal side, and double vision towards the nasal, remained in some cases only a few days; in the most, however, several weeks. Where muscæ volitantes, photopsia, nystaxis or nictitatio palpebrarum existed, these affections decreased in proportion as the centre of the posterior hemisphere increased in acuteness of sensation *. Many of my patients have confessed to me that they feel themselves far more happy and composed in mind since the removal of the deformity.

I have here given a correct statement of my experience from accurate observation, detailing the advantages as well as the disadvantages that have attended my operations, and may safely say that in not one case strabismus has returned. The pupil has its normal position; the motions of the eye are free, both eyes acting in harmony. Even in the three above-mentioned cases, where the success of the operation might be called questionable, the slight inversion of the operated eye can only be detected by a careful observer. In proof of my assertion, I annex the addresses of my first cases, related in several numbers of the MED. GAZETTE for this year:—

* See "Physiological Observations on Eyes operated on for the cure of Strabismus," MEDICAL GAZETTE for June 26th, 1840.

CASE I.—Louisa M'Cleish, 4, Chapel Place, South Audley Street. The left eye was slightly inverted, but the right to such an extent that one-third of the cornea was hidden by the inner canthus. This is one of the less successful of the above-mentioned three cases.

CASE II.—Emma Mattoks, 31, Circus Street, New Road, Marylebone. The right eye slightly inverted; in the left, the inner margin of the cornea was in contact with the caruncula lacrymalis. Both these cases were operated upon on the 10th, and published 17th April.

CASE III.—Thomas W. Gest, 9, Phenix Street, Soho. One-fourth of the cornea in the left eye hidden by the inner canthus. Operated upon on the 6th May; published by Mr. Steinhaeuser on the 22d May.

CASE VI.—William Nicholson, clerk at Messrs. Leaf and Co.'s, 47, Wood Street, Cheapside. The left eye, in which one-fourth of the cornea was covered by the inner angle, was operated upon on the 14th of May. ·

CASE VII. — Susan Ridgow, 61, Princes Street, Leicester Square. Right eye, where one-fourth of the cornea was hidden by the inner canthus, operated upon on the 20th May. Both these cases were published 12th of June.

In concluding I may perhaps be permitted to answer the contended question—" to whom the priority in execution of Dieffenbach's operation for strabismus in England belongs?" By the testimony of the Medical Journals Mr. B. Lucas published his first case, operated upon on the 11th of April, in the Lancet for the 18th of April. The British and Foreign Medical Review for July *a. c.* says " we believe he was the first to perform it in England." My two first cases were operated upon on the 10th of April, and published in the MEDICAL GAZETTE on the 17th of April. The Medico-Chirurgical Review for July, *a. c.* says, " As Dr. Franz's cases have had the priority of publication we think it only fair to notice them." The Dublin Medical Press of April 29th states, " We believe Dr. Franz's operations are the first of this kind performed in Great Britain."

As this question is of no practical value, I think it of very little importance who first performed the operation for strabismus in this country.

Your obedient servant,

AUG. FRANZ, M.D.

19, Golden Square, Sept. 22, 1840.

AN INQUIRY INTO SOME OF THE CONSE-
QUENCES AND CAUSES OF FAILURE
OF THE

NEW OPERATION FOR THE CURE OF STRABISMUS OR SQUINTING.

By. E. W. DUFFIN, ESQ.

Surgeon.

[For the Medical Gazette.]

(Continued from page 18.)

As the arguments adduced in my last communication to explain the facts connected with the two singular cases therein related are not founded on the ordinarily received doctrines of modern physiologists, and do not take into consideration the action of the oblique muscles as opponents of the abductor, I am aware they are in these respects highly objectionable; still, as they appeared reasonable, and so directly to support the old theory, that apparent identity of origin and inter-communication of nerves in their course are calculated to produce similarity of function, or mutual co-operation in the action of the muscles to which they are distributed, I ventured to introduce them, even at the hazard of being considered, *pro tempore*, ignorant of the current opinions maintained at the present day on this subject. The researches of Drs. Monro, Whytt, Alison, Müller, and others, have, I believe, been quite successful in establishing—

1. That although nerves may lie in juxta-position in the same sheath, they never absolutely anastomose.

2. That apparent identity of origin does not by any means imply identity, or even similarity, of function. And,

3. That all nerves perform their functions independently of each other*.

The opinion of Mr. Walker, of Manchester, that the parallelism of the eyes is preserved by the action of the superior oblique muscle†, although very ingenious, is of course completely negatived by the results that have uniformly followed the division of the adductor. Were Mr. Walker's views correct, we should expect that the eyes would preserve their consentaneous movements inwards after the operation, because the superior oblique still remains uninjured for that purpose; but we find the reverse:

* Vide an Article by Professor Alison, 2d vol. of the Edin. Med. Chir. Transactions.

† Vide Philosophy of the Eye, by John Walker.

the eye cannot be turned inwards either in conjunction with its fellow, or consentaneously in this direction when its fellow is turned outwards. And when, under certain circumstances that will be presently noticed, the pupil does turn a little inwards after the adductor is divided, we now know that this movement is more the result of the conjoined action of the inner fibres of the superior and inferior recti, than dependent on the contractions of the superior oblique; and that cutting these inner fibres, though not the most judicious mode of proceeding, always rectifies the position.

As the contractions, however, of the superior oblique, judging from the direction of the fibres of the second belly of the muscle, as well as from its tendinous insertion, are calculated to draw the eye a little inwards, and to rotate the globe slightly downwards, and the course of the fibres of the inferior oblique is calculated to roll the eyeball in a contrary direction, it is possible that these muscles may, in some degree, act as antagonists to the external rectus when the adductor is divided, and be a principal cause why the pupil does not turn outwards by the action of this muscle as a general rule*.

For want, then, of a more precise and satisfactory *rationale* of the circumstances attending the first girl's case recorded in my second communication, although liable to innumerable objections, it appears to me that we must be content for the present to adopt the theory of Professor Alison, " that the sympathetic movements of the eyes, like sympathies in general, proceed from *mental sensations*, and that the organs sympathize with each other only so far as the sensation, which is the natural and appropriate stimulus of the one, is excitable by irritation of the other."

It is not, however, my intention to weary the reader by burdening my practical facts by a lengthened physiological inquiry into their cause, however interesting and tempting such a

* Whilst correcting the press, I may just state that I have this day performed some experiments on a dog, the results of which have completely satisfied my mind in regard to the action of the oblique muscles. The facts shall be published next week. In the meantime I may express my conviction, that no one has yet divided either of these muscles, and I would advise no one to attempt the operation, as a cure for strabismus, without perusing the observations I have to offer upon the subject.

discussion may be, having it in view to correct and publish these communications hereafter in a separate volume, illustrated with appropriate engravings, when I shall have more leisure and space to follow up the investigation. My present remarks, therefore, will, I trust, be considered the hasty results of practical observations, which I am anxious should be made known, crude as they are, before they can be appropriated and promulgated by others.

At first sight it may appear unnecessary to warn those who have not directed their attention to the subject of strabismus, that they are very liable to select the wrong eye for operation; but I can assure them that it is often no easy matter to determine which side is most affected, or whether the individual squints with only one or both eyes.

Mr. Crommelinck informs us that, having had an opportunity of examining a great number of persons affected with squinting, he is disposed to confirm the statement of Buffon, "that strabismus never affects both eyes simultaneously. Where one eye," says he, " is much affected, the other, at first sight, no doubt seems equally so; but when operation restores the distorted eye to its natural position, the opposite one loses its apparent deviation either immediately, or after the lapse of a short time*."

In the majority of instances this opinion is correct; but I cannot assent to the statement that strabismus "never affects both eyes simultaneously," because I have seen very numerous examples to the contrary, and have been obliged to operate on the second eye also; and this I have done, not only with the effect of totally removing every vestige of strabismus, but with the still further advantage of leaving both eyes so precisely similar in general contour, size, and appearance, that even the most critical observer could detect no trace of former distortion, nor perceive any evidence that an operation had been performed, beyond the slight remains of cicatrix, resulting from the wound made in the conjunctival covering.

Unless a case will stand this test, I do not consider it entitled to the epithet *perfect*, since I can produce, for the

satisfaction of the curious, or incredulous, numerous examples of this degree of perfection. Every thing short of this, although the original obliquity may have been removed, I consider an evidence of only partial success.

But to return to the question, whether squinting ever occurs in both eyes simultaneously. I believe the more general rule to be, that the distortion very rarely *assails* both eyes at the same precise period, but that in the course of time both may become *affected;* the second being gradually implicated by sympathy, or by the unconscious efforts which the patient makes to render the axis the same, in order to obviate double vision. And although for a length of time the distortion may continue to be of such a nature that removing it from the eye which was first attacked will remedy the defect in that subsequently involved, yet, in a great many cases, it becomes a permanent disorder in both, especially if, during its continuance, the eye has been the subject of strumous, or other inflammation, calculated to produce any thickening, contraction, or other morbid change, in the sub-muscular cellular tissue. I have always found, when the operation consisted of more than dividing the tendon, and the strabismus was at the same time of long duration, that ultimately the second eye required operation also, before the position of these organs was rendered perfect in every respect. It is always proper, however, to operate on only one eye at a time, and of course we ought to select the most faulty, namely, the one primarily affected, and afford the other the chance for a week or two of rectifying itself without an operation.

"The degree of power," says Mr. Guthrie, " that a person possesses over his eyes, is occasionally very doubtful on the first inspection of them, both eyes squinting in turn or together, and it is only after a little delay that the really defective eye can be clearly ascertained; whilst in others, the motions of the eye are altogether so irregular, and so little under control, that it becomes doubtful which muscle should be divided, or whether it would be proper to attempt any operation at all." When, then, we cannot determine this question by inspecting the eyes, and desiring the patient to look at an

object placed alternately on each side of his nose, so as enable us to estimate which pupil is capable of being turned most inwards, we shall generally be assisted by the knowledge which the individual possesses of his own case, except in children, when we must either rely on our own judgment, or on such information as we can obtain from the parents or friends of the party. The sight of the eye most affected is very often somewhat impaired, and in many cases partially amaurotic. Indeed, one of the most important results of the operation, in numerous instances, is the subsequent gradual improvement of vision. A person who squints considerably cannot see an object placed at a little distance from him with both eyes at once: hence many persons affected with strabismus imagine themselves to be near-sighted, because, in order to see an object distinctly, *i. e.* to obtain the advantage of seeing it with both eyes at the same time, they are obliged to hold it near the face, that they may bring it within the axis of each simultaneously. But as soon as the distortion is removed by operation, not only is this near-sightedness cured, but the imperfection of vision proceeding from the image not being depicted on the most sensitive part of the retina, that destined to receive visual impressions and transmit them to the sensorium, very soon ceases. Although, as just remarked, the degree of power possessed by a person who squints over his eyes is occasionally doubtful, in the majority of cases it is by no means limited; on the contrary, by an act of volition, we shall find that the eye is capable of the same movements, and to an *almost* similar extent, as if it were in every respect free. If the palpebræ of the best or sound eye be closed, and gentle pressure made on the globe so as to steady it, the faulty eye, provided it be not prevented by any unnatural adhesion, or other morbid change of structure, generally starts immediately from its abnormal situation into the proper position that it ought to occupy, nearly midway between the extreme boundaries of the inner and outer angle, and is capable of being turned outwards in almost any natural degree. But as soon as the sound eye is uncovered, and the voluntary effort is discontinued, the faulty one returns again to the inner canthus. It can also be directed

outwards, in unison with its fellow, when the individual looks at an object placed at the corresponding side of him. In short, the patient can move his eyes in any direction he chooses; but as soon as the voluntary effort ceases, they yield to the morbid power by which, when quiescent, they are controlled, and the obliquity returns.

From the want of a knowledge of these facts many surgeons are misled in their early attempts to relieve strabismus, and erroneously consider the operation completed when in reality it is only half performed; or when, perhaps, the tendon has not been even cut at all. When assisting others, I have frequently pointed out that the operation still required some further steps to render it perfect, and have been usually met by the observation, " that nothing further could possibly be requisite, as the tendon was clearly divided, and the patient possessed the power of turning the pupil outwards; the eye being straight, and in its proper position, when the other was covered over." The only conclusion to be drawn from this reasoning is, that the operator was not aware that the division of the tendon alone, in many cases, is insufficient to liberate the eye and remove the obliquity. The oblique movements in the directions upwards and inwards, and downwards and inwards, are by the unpractised operator ascribed to sympathetic influence; being satisfied if his patient cannot bury the pupil in the nasal canthus in as great a degree as he could previously. Now we have already seen that these *diagonal* movements do not proceed from sympathy, but from the natural contractions of the superior or inferior rectus, whilst the eyeball still continues tethered by some portion of fibro-cellular attachment; and that if this be divided, the operation will be complete.

The most decided test of a perfect separation of the tendon and adventitious adhesions is not that the eye can assume its proper position when its fellow is covered over, or that it can be directed outwards by an act of volition, but that there result from the operation a total inability to move the pupil *horizontally* inwards from the natural position that it ought to occupy in the centre of the orbit, and at the same time an incapacity of directing it in the slightest degree in either of the diago-

nal lines above indicated. When, in such case, an attempt is made to look at the nose, the pupil is immediately depressed, the globe being pulled directly downwards by the action of the inferior rectus muscle.

If these conditions be fulfilled, and *they ought to be if the obliquity be confined to one eye*, we may rest assured that the ball is completely liberated. But we cannot always obtain this decided result. It sometimes happens—indeed, nearly always when *both* eyes are implicated—that the operation is as perfectly performed as it can be, and that still the patient has a slight cast when he looks with both eyes at an object placed directly before him. This we shall find to proceed from a concurrence of action of the inner fibres of the superior and inferior recti, aided, perhaps, by the obliques, which, when the squint has been considerable, have likewise become involved in its production. Be it observed, however, that there is no occasion to divide these fibres, since, if there exist no permanent obliquity in the other eye, this morbid action will cease in a day or two. But if any confirmed obliquity exist in the other eye, I have always found it best to operate on it also; on doing which, this vestige of the original evil has almost always instantly ceased, never to return. It appears that this action of the inner fibres, just described, is very feeble, and in a great measure dependent on the sympathy that subsists between the two eyes, since it is only capable of being exerted so long as the tendon in the other eye continues undivided. Were we to remedy the obliquity thus produced by dividing the inner fibres of the superior or inferior recti muscles, as has been recommended, the eye would be very prone to start forward, and impart an ungainly appearance to the individual; whereas, by operating on the other organ, we not only obviate the risk of this occurrence, but completely rectify both eyes; and should the eye first liberated be a little enlarged by the operation, we have it in our power to make both correspond in this particular.

Another test that the operation has been thoroughly performed is the capability of the patient acquires of not only directing the pupil much more outwards than he could previously, but,

if the tendon of the external rectus be free to act, of turning it much more outwards than natural. Even the decided indication already insisted on, viz. a total inability to move the pupil from the centre of the orbit horizontally towards the nasal canthus, may be frustrated by an adherent condition of the tendon of the abductor muscle. A little experience, however, teaches the surgeon how to ascertain, by sweeping the sclerotica carefully with his blunt hook, when the liberation of the eye is complete, without being obliged to rely upon the foregoing investigation, although he should never neglect to institute it, as he is thereby generally enabled materially to corroborate his judgment.

Of the Double Operation for Strabismus.

For the most part, as has already been shown, although there may apparently exist an obliquity in the axes of both eyes, it will, on a careful comparison of their capabilities, be found that the affection is much more marked in one than in the other; and that, on dividing the tendon and liberating completely the globe of the most faulty eye, the axis of the other, though for a few hours at first often rendered more objectionable, will soon become correct, and continue so. The previous obliquity in such case had resulted simply from sympathy, or, to speak more precisely, from the constant co-operation that subsists between the two eyes in all their movements, in order to render vision with two organs a single function. I conceive it to be quite possible, although I have no positive proof on which to found my opinion, notwithstanding the statement of Buffon and others, that strabismus convergens may assail both eyes at the same time. It is evidently, at its commencement, a spasmodic disorder, which attacks the internal rectus, and perhaps other muscles of the eye; and I can see no reason, although it may not be a usual law, why the corresponding muscles of each eye should not be simultaneously affected, especially when the distortion proceeds from functional derangement of the alimentary canal, or any other disorder capable of disturbing the nervous system generally. I have seen, as will appear by reference to the preceding parts of these communications, cases in which the internal recti have been

simultaneously affected with paralysis, to the exclusion of the other muscles of the eye; why, therefore, may they not both be attacked with spasm at the same time?

Be this as it may, at all events it sometimes happens, when the defect is well marked, that the sympathetic influence it produces on the opposite eye, by long and active continuance, degenerates into a permanent shortening of the muscle, and corresponding degree of contraction and thickening of the sub-muscular cellular tissue, similar in every respect to that of the primitively affected organ; so that it becomes requisite to liberate the secondarily distorted eye also. If we neglect to do this, in the course of time, when the muscle first divided has formed a reunion with the sclerotica, a relapse of the original deformity may be induced in the eye that had been the subject of operation.

I am not aware that any person practised the double operation previous to myself, which I first performed more than two months ago; nor do I believe that it has been generally recommended by any but those surgeons who have had the opportunity of examining my cases. Such, however, has been the impression on these gentlemen, on seeing the perfection that may be thus obtained, that none have dissented from the propriety of the measure, and most of them have since adopted it whenever opportunity presented.

From the facts detailed in the former parts of this communication (Sept. 19th and 26th), it is evident that the second eye cannot be operated upon in all cases with impunity. We have seen that when the second eye is thoroughly relieved, the external recti are apt to assume an ascendancy of power; and when the patient looks at all outwards, to draw the eye so much to the external angle as to produce a very unpleasant leer, and at the same time to render vision double. So long as any bond of union remains between the adductor of either side and the sclerotica, however slight it may be, this untoward event does not happen: from which we may infer, although difficult to suggest a satisfactory theory to account for the fact, that the mutually controlling influence which proceeds from the intimate intercourse subsisting between the adductor branch of

the third pair and the sixth nerve, ceases, in some instances, when the physical restraint of the two muscles is overcome, by dividing the tendons of both.

In order to meet this difficulty, then, although unable to see in what manner the adductor of the right eye, for example, should exert any physical control over the abductor of the left, the nervous communication which influences their consentaneous movements remaining uninjured, it occurred to me, in performing the operation on the second eye, to avoid destroying *completely* the physical restraint by which it is held in bondage, and thus to preserve what appeared to be requisite to obviate the undue direction of the eye outwards when the individual looked at an object placed at the side of him. I found the experiment successful; and out of more than sixty cases, I have never met with the same unfortunate result as that already recorded in the second portion of this communication.

In operating on the second eye, then, the great secret by which alone a fortunate and perfect result is ever to be secured, is to ascertain with the hook, before dividing the tendon, whether there exist any adventitious adhesions likely to steady the eye after the tendon is divided; and if so, to carefully preserve a sufficient band of these, to operate as a restraining power. If this be done, we shall find that the action of the abductor, that might otherwise have turned the pupil outwards, will just be sufficient to draw it to the centre of the orbit; and, in all the consentaneous movements of the eye, this undivided band will exert that restraint which is required to preserve a unity of action and correspondence of the axis of the two organs.

Pathology of Strabismus Convergens.

From what has already been stated in various parts of the present and three last portions of this communication, very little remains to be said on this head. The views that I entertain must ere this be familiar to my readers; still it will be requisite to recapitulate them, in order to notice those of others, and to enable us better to understand the next part of our inquiry, viz. the *causes of relapse.*

From whatever remote causes the disorder may proceed, and these are

numerous, being both functional and organic, the first immediate step towards the production of strabismus is either spasmodic contraction, more or less permanent, of the adductor, and, in some cases, of the inner fibres of the superior and inferior recti, or loss of power in the abductor muscle. I have not met with a single case of congenital strabismus, though, in many instances, the deformity is reported to have supervened within a few days after birth. In by far the greater number of cases— for out of upwards of 400 [*] I have only seen three to the contrary—a contracted state of the inner muscle obtains. This, in the first instance, is a mere spasmodic condition of the part, not by any means necessarily permanent, but it would seem it very soon becomes so ; in which case the adductor muscle becomes shortened ; and although capable of extension when the antagonist abductor acts, it still retains the eye turned somewhat inwards when the organ is quiescent. Should any in-

* It may be here requisite to state by what concurrence of circumstances I have had the good fortune and practical advantage of examining so many cases of this disorder, from whence, indeed, I have collected the *materiel* for the present series of communications.

After having operated upon between forty and fifty individuals in London, and assisted various of my professional brethren to an almost similar extent, I accidentally visited my friend, Dr. J. C. Williams, of Nottingham, who enjoys a high reputation and extensive practice as an oculist in that town, and for twenty miles round ; as does also his cousin, Mr. John Northon Thompson, as an ophthalmic surgeon. The operation being new in Nottingham, these gentlemen were desirous of seeing it performed. On mentioning to other surgeons of the town their intention of collecting together a few cases for operation, many of them expressed a wish to be present, and kindly used their exertions to provide patients. The consequence was, that in the course of a few hours cases presented themselves in incredible numbers, and during the three days I remained, Mr. Thompson and myself operated upon upwards of 70. Ten days afterwards I revisited the town to examine the result of our practice, and not only had an opportunity of repeating the same extraordinary surgical feat, but had the advantage of examining about 150 cases that had been operated upon by my surgical friends during my absence, Mr. Thompson himself having relieved 95. Before finally leaving Nottingham on this occasion, I visited my friend, Mr. Douglas Fox, of Derby, who likewise, aided by his professional brethren, had collected a larger number of persons than could be operated upon during my stay. Since my return to town I have relieved upon an average three cases a day. I now avail myself of the opportunity of cordially thanking the professional gentlemen in Nottingham and Derby for the very kind manner in which they received me, and for the invaluable facilities they afforded me of obtaining practical information on the subject of these communications.

flammatory affection of the membranes of the eye supervene during the existence of this state of spasmodic contraction of the adductor, the submuscular cellular tissue is liable to be not only thickened, but rendered unyielding and adherent. When this change is established, even should the spasmodic condition of the muscle cease, the tendon will, of course, remain closely attached to the sclerotica, and be unable to resume its normal condition.

During the progress of this alteration in the character of the cellular tissue, as the eye is necessarily in motion, the opposite abductor being constantly called into action, the adhesions that take place between the sclerotica and the tendon of the adductor, and that would otherwise immoveably fix the eye in the inner canthus, become gradually elongated into bands, in the same manner as the adhesions which take place between the pleuræ, after pleuritis, become elongated by the constant action of the chest during respiration ; or like those often met with, which unite the heart to the pericardium, and are the result of pericarditis. Now it is these bands of fibrocellular connection passing between the sclerotic tunic and the under surface of the muscle and its sheath, that in such numerous instances retain the eye in an abnormal position after the tendon has been divided, and render so many cases only partially successful. I have met with these bands very far back, even beyond the greatest diameter of the globe of the eye ; and in two cases found them almost cartilaginous, and so unyielding that the patients were wholly unable to move the pupil out of the inner canthus. When a case presents itself in which these bands exist, we find that, after dividing the tendon, the pupil still turns somewhat inwards when the eye is quiescent, and that when the patient makes an effort to cause the two eyes to converge still further, by directing them towards the inner canthus of each, being deprived of the power of doing so on one side, by the division of the tendon, the effort is aided by the united action of the inner fibres of the superior and inferior recti, and the pupil is in consequence drawn either diagonally upwards and inwards or obliquely downwards and inwards ;

the direction which the eye takes in this respect being dependent on the comparative influence of these muscles and the site of the retaining force. A separation of this band usually liberates the eye, and completes the operation.

We are not, however, always to expect to find a fibrous interlacing of adhesions, such as I have just described, since this is the result of inflammation, and only to be met with in cases that have suffered from ophthalmia after the supervention of strabismus. In most instances the contracted tendon is all that requires division; but should we find the contrary, and learn that the individual never suffered from membranous inflammation of the eye, a little examination with the hook will detect the cellular tissue thickened and contracted : this change in its texture having gradually supervened on the subjacent connecting membrane accommodating itself to the shortened state of the muscle and its tendon, and the new position of the eyeball. When either of these morbid alterations of texture are fairly established, we may rely on it that nothing short of their complete separation will effectually liberate the eye from bondage.

This I believe to be the true pathology of the disorder, from having so frequently encountered the obstacles just related, and being unable to detect them in the sound and dead eye. When we carefully examine the submuscular cellular tissue in the recent subject, if no strabismus existed during the life-time of the individual, we find it to be so extremely delicate and yielding, as to convince us that it must undergo the changes here stated, otherwise it could never offer the resistance it often presents to the completion of the operation. Mr. Hocken, in some useful remarks on strabismus (published in the MEDICAL GAZETTE for Sept. 11th, 1840), has stated it as his opinion that strabismus often arises from hypertrophy of the adductor muscle, aided perhaps by atrophy of the adductor. Now, I am not prepared to assert that such a change in the development of the muscles of the eye never exists, though I do not believe it to be the general condition of the inner muscle in cases of this description. I can readily imagine, with Mr. H., that an increase of nervous influence, followed by hypertrophy, may attend

the excessive employment of any of the orbital muscles, whilst their antagonists may become atrophied from disease ; and that in this manner we might easily account for strabismus originating in imitation (if it ever does arise from this cause), habit, improper education of the eyes, long retention of the head in one position, disparity of vision, opacities of the cornea, &c. &c. &c.

But we find, from the general history of the disorder, in the vast majority of examples, that the obliquity invades suddenly, before any change such as hypertrophy can possibly have been established. In some cases the disorder is intermittent, and gradually becomes permanent, in others it would appear to be confirmed from the first. Were simple hypertrophy of the muscle the common cause, then cutting the muscle across would in every case liberate the eye; but those who operate extensively will find this far from being the case. Severing the muscle, in a great many instances, is only a small part of the operation.

Want of attention to this fact, I again repeat, is the main reason why we see so many persons only partially relieved.

If the bands, to which I have so often alluded, are left undetached, they form the ground work of a relapse of the distortion, by detaining the globe still tethered, until the cut tendon has time to form a new union with the sclerotica.

Causes of Relapse.

A sufficient length of time has not elapsed since the cure of strabismus by surgical means has been practised, to enable us to estimate the proporion of permanent success with which it is likely to be attended. When the operation is thoroughly performed, and only one eye has been originally affected, there does not appear much probability of any renewal of the disorder. The morbid consentaneous influence that might in the course of time have involved the second eye being no longer in operation, the temporary obliquity it derived from this source will soon subside, and both eyes remain sound ; but if it should be found that both eyes were primitively affected by the same exciting cause*, or that the disorder which was at first only sympathetic in

---

* Presuming that both eyes may be simultaneously affected.

the second eye, has become permanent, then it is possible, even after operation, when a reunion has taken place between the divided ends of the tendon and the sclerotic coat, that the eye which was the subject of operation may in turn become again sympathetically implicated; though I should imagine never to so great an extent as previously. Relapse, then, being evidently dependent on the circumstance of both eyes having become permanently affected previous to operation, the proclivity to this event will of course be in proportion to the degree in which the unliberated eye remains implicated.

Even although no union should ever again take place between the divided muscle and globe of the eye, still I conceive it quite possible that the other muscles, being under the influence of the same consent or sympathy already alluded to as subsisting between the eyes, in order, when practicable, to render vision with a double organ a single function, might be gradually involved in a conjoint morbid performance of their duties, and by the force of involuntary practice might ultimately so accommodate themselves as to perform functions for which they were not originally destined.

Another source of relapse, of a much more simple nature, though by no means of frequent occurrence, is the contraction of the new or substituted parts at the inner canthus of the eye during cicatrization, when the conjunctival folds and loose cellular tissue have been unnecessarily removed. A few days ago I remedied a relapse of this description, by again freely dividing these : the eye was instantly restored to its proper situation.

The possibility of cicatrization again limiting the movements of the eye, though a rare occurrence, is another, but, perhaps, as it can be easily obviated, a trifling objection to unnecessarily destroying any of the outer coverings or appendages of the eye.

When strabismus arises from any defect of vision in one eye, and the distortion has been produced by the efforts of the patient to accommodate the faulty axis of the diseased eye, we may expect, as the strabismus is in such case a resource of nature to obviate the difficulty, that, as soon as the

reunion takes place between the divided tendon and the sclerotica, and the muscle is again free to act, the original efforts will be renewed, and the obliquity recur. For the most part, strabismus is the cause of defective vision, and on its removal the sight improves. When, therefore, we find the converse of this fact, and the patient complains that his vision is in consequence become more confused, we have reason to apprehend (if the previous history of the case confirm the opinion) that we have operated on an example of the above description, and that a relapse may ultimately occur.

Fortunately, on the re-establishment of strabismus, the vision would be restored to its former condition. Inquiries, then, of this description, should be very carefully instituted before the operation can be recommended. In fact, the proclivity to relapse will very much depend, in numerous instances, on the nature of the remote cause, and on the probability of its persistence after the eye has been set at liberty. From what I have seen, however, I do not imagine that relapses will be of frequent occurrence ; on the contrary, I am of opinion they will be very rare. Several cases of alleged relapse that have been shewn to me, were not returns of the affection, but only imperfectly performed operations, or the result of mere sympathetic connection with the other eye. A few of these cases I have myself since remedied by operating on the second eye, which had erroneously been regarded as not implicated, on the principle that " squinting never affects both eyes simultaneously." Mr. Elliott, of Carlisle, I perceive by last week's Lancet, has been led to practise the same proceeding, and very judiciously entitles his communication " Division of both Internal Recti in Squinting, in preference to that of any other muscle, when the division of one adductor only is not instantly and completely successful." The difference between Mr. Elliott's practice and my own is, that I allow a little time (three weeks or so) to elapse between the operations, not only to afford the eye presumed to be unaffected the opportunity of correcting its obliquity and thus to satisfactorily decide the question whether it be itself really
implicated or not; but also to enable the muscle, first divided, time to form a new insertion into the sclerotica. If this latter direction be not attended to, it will be found that one or both eyes will often turn unduly outwards when the abductors are called into contraction. During the interval between the two operations, as soon as ever the patient can bear to use his eye, and this he can generally do within 24 or 36 hours after the tendon has been divided, it is desirable to place a soft compress of lint and a bandage over the *sound* eye, to prevent its morbid movements from influencing the one that has been the subject of operation. If we neglect this precaution it is possible that the divided tendon may form a second attachment too near its former insertion, the eye being inclined unduly inwards during this period. When the sound eye, however, is covered over in the manner suggested, the one that has been liberated preserves its proper position in the centre of the orbit, and the reunion between the cut tendon and sclerotic tunic takes place considerably posterior to the original site, as the muscle, it may be presumed, shrinks in some degree when set at liberty.

On the Operation for Strabismus Convergens.

On this subject I have very little to say that has not already been stated in the preceding portions of this communication. The operation I perform is that suggested by Mr. Bennett Lucas, and which I believe to be decidedly the best in every respect.

When it is requisite to keep the eyelids seperate by any mechanical means, I employ the double speculum proposed by my friend Mr. John Northon Thompson, of Nottingham, and which, with his permission, is here represented.

It is the best instrument of the kind I have seen, and has the advantage of enabling us to hold the eyelids open in spite of every spasmodic effort to close them, without creating any pain. It has the further advantage of enabling us to get at the eye freely, the hands of the assistant being very far removed from the site of the operation. I cannot imagine the necessity of putting the patient to the pain of depressing the lower eyelid by means of artery forceps, as recommended by some sur-

geons; neither have I ever found it necessary to fix the globe of the eye by means of a sharp hook.

The patient is desired to direct his eye outwards; the conjunctiva is then to be pinched up by means of a fine forceps, and cut across with a pair of strong scissors, nearly midway between the edge of the cornea and the semilunar fold of the membrane. This opening should be made freely, and care taken in making it to completely divide the subconjunctival loose cellular tissue, so as to fairly expose the tendon from its upper to its lower margin.

The blunt hook is then to be inserted under it, so that when raised and drawn to the external opening, a small portion may be snipped out of it. Should the pupil, when this is done, be found not to occupy its proper situation, the hook should be introduced again, and any bands of fibro-cellular tissue that still fix the eyeball should be brought to the external opening in the same manner as the tendon has been, and divided; this being repeated till the eye is perfectly liberated. The only point in the opera-

tion that requires more precise instructions is the direction in which the blunt hook should be introduced, and the manner in which it should be made to gently sweep the sclerotica in search of adhesions. This is the grand step in which most surgeons in their early operations fail. They generally introduce the hook by holding it at a right angle with the eye, its concavity looking upwards, and thus almost invariably miss inserting it under the tendon ; whereas, if introduced by holding it almost parallel with the eye, the point being directed downwards, as represented in the woodcut, until it reach the inferior margin of the tendon, and then the handle be turned carefully upon its axis, and the hook next swept gently over that portion of the sclerotica which it is necessary to clear, no difficulty will ever be experienced in passing it under the tendon, or any thing else that it may be requisite to divide. After its point is turned upwards, all that requires attention is to keep the flat side of the instrument towards the eyeball *, and its extremity in gentle contact with the sclerotica, taking care to make it emerge through the external wound, by keeping the handle well depressed, and causing it to obliquely cross the nose. I have seen a great many operators at first thrust the extremity of the hook directly against the globe of the eye ; and some, I am informed, have actually pushed it through the sclerotic coat, and allowed the humors to escape ; whilst almost every one, from want of attention to the last direction, that of making the handle obliquely to cross the nose, catches its extremity under the superior tarsal cartilage, from whence only, after numerous ineffectual efforts, they finally disentangle it.

Treatment after the Operation.

If the operation be performed neatly, and with address, no more of the conjunctiva being cut or displaced than is necessary for the purpose of cutting the tendon, little or nothing requires to be done afterwards. A fold or two of lint, moistened with cold water, may be applied over the closed eyelid, and retained there for a few hours, to obviate as much as possible ecchymosis, and prevent inflammation, which latter,

* The hook I use is a blunt-ended flat hook.

however, very rarely supervenes, although the ecchymosis is sometimes considerable, especially if the conjunctival tunic have been unnecessarily raised, so as to allow of infiltration of blood into the cellular tissue under it. On the second day we shall find a considerable deposition of lymph from the sub-conjunctival membrane uniting the cut edges of the conjunctiva, and be led, perhaps, from its abundance, to expect that a tumefied cicatrix will result, but such is seldom the case. In the course of a short time this deposition gradually disappears, and, along with it, the ecchymosis.

In order to hasten both these results, we may recommend, after the third or fourth day, a slightly astringent or stimulating solution to be dropped into the eye twice or thrice a day. From two to six or eight grains of sulph. zinci dissolved in an ounce of rose water answers very well for this purpose. When the conjunctiva has been inadvertantly cut away, the reparative process is often very tedious, and the cicatrization is retarded by the exuberant growth of mushroom-like granulations. These may be removed by the daily use of sulphate of copper, or, what is much better, and far less painful, we may allow them to grow till they are large enough to be cut away, and then remove them by means of fine forceps and scissors. They often bleed freely, but their removal, as they are very insensible, is unattended with pain. I used to apply blue stone to hasten the disappearance of the reparative lymph, but I found that the irritation it created kept up the turgescence of the blood-vessels, and rather retarded than hastened the desired absorption.

The majority of cases are perfectly cured by this plan of treatment in the course of a fortnight or three weeks, and, during this period, never suffer any inconvenience beyond that which arises from ecchymosis, the eye looking blood-shot, turgid, and glistening.

Very often during the performance of the operation, whilst the tendon is being divided, the patient complains of pain in the forehead, similar in degree and kind to what would be produced by pressing the finger very firmly on the part, This uneasiness sometimes remains for several hours afterwards, and is best relieved by warm fomentations to the eye.

In a few instances I have found the same sort of sympathy to be excited in the stomach that so frequently supervenes after couching, and the patient has been troubled with vomiting for twelve hours after the division of the tendon. When this symptom happens we generally find, on inquiry, that the patient has experienced similar attacks of vomiting from trifling causes on former occasions, and is, at times, the victim of the ordinary forms of hysteria. Under these circumstances effervescing salines or opiates may be tried, but they have not in my practice been of much use. The latter remedy has generally aggravated the distress, by occasioning vertigo or headache, without relieving the symptom for which it was administered. Indeed, temporary confusion or giddiness of a few hours' duration, is no uncommon occurrence after the operation, without the assistance of a narcotic. Time and tranquillity appear to me to be the best remedies; these annoying symptoms usually ceasing after the first sound sleep, and being in the meantime much mitigated by keeping the patient quiet, and in a dark room.

Should membranous inflammation supervene, it must, of course, be treated by blood-letting, leeches, warm fomentations, active purgatives, and the other ordinary means appropriate in simple inflammation of the textures affected.

14, Langham Place, Regent Street,
        Sept. 24, 1840.

POSITION OF THE PLACENTA.

To the Editor of the Medical Gazette.

Sir,

In a late number of the MEDICAL GAZETTE I have seen a notice of the investigation I have been lately engaged in at the Coombe Lying-in Hospital of this city, respecting the position of the afterbirth in the womb in the different stages of gestation; and the result of that investigation has been so fully put forward therein, that I consider it unnecessary to enter here into any further detail of it.

As stated in that notice, the observations I published on the subject were subsequently impugned, and objected to, in the Dublin Medical Journal, by reviews from the Brittain Street Lying-in Hospital; and the last of these reviews contained a statistical table of one hundred cases in which the position of the afterbirth is stated to have been observed at that institution, with results so different from those I mentioned as having occurred at the Coombe, that it is put forward as conclusive against me; altogether subversive of the correctness of my statement in this respect, and the opinions arrived at therefrom.

On the appearance of this last review I tendered a reply to it to the Editor of the Dublin Journal, which, after some hesitation, was received by him, on conditions that it should be published in two separate parts; one in the following number, and the other in the next succeeding one, and which, on my part, was acceded to. Accordingly the first appeared in that for July last, but the remainder, which contained the refutation of this statistical table, as well as of other points insisted on, and which was forwarded to him on the coming out of the July number, was, after some weeks, returned to me with a letter refusing it a place in the Journal, and assigning as a cause "that it exceeded the limits the periodical could give it." It would print to about eighteen pages of it!!

In the notice you have been pleased to take of the subject, this statistical table is considered as making very much against my opinions; and as matters now stand, the impression must be, that on my part I looked upon it as unanswerable; for the Editor of the Dublin Journal not only refused the publication of the continuation of my reply, but likewise the request I made of him when he so refused, namely, of noticing in his journal that I had tendered it to him, and that he had declined it for the above reason. If it would not, however, be trespassing on the Gazette, I think I shall be able to show, in a few sentences, that this table is altogether erroneous, and as an interesting point in physiology is in some degree involved in it, may I be permitted to hope that with you it will not be refused? The cause of science I am certain will not be unpalatable to any of the friends of the LONDON MEDICAL GAZETTE, nor the vindication of truths in any way inconvenient to them.

I believe it is a matter fully admitted, that the ovum first attaches itself to the

uterus in the immediate neighbourhood
of the Fallopian tube it traversed; it is
retained there, when it enters the
womb, by the part of the decidua
which covers these uterine apertures,
and there the placenta is first formed.

The substance of my remarks, then,
upon the subject in question, rests
upon two points: the first, that at the
period this attachment takes place the
uterine aperture of the tubes, and con-
sequently the newly-formed placenta,
is at or near the fundus of the womb;
and the second, that at the close of
gestation, they are, and particularly
the latter, low on the posterior wall.
I have stated in my original paper that
the membranes, when delivered, will be
found to be so marked as to enable us
to ascertain this second point, and that
according to their testimony, I found
it (the placenta) there to be situated, as
above stated, in 96 or 97 times out of
the 100.

Both of these data, however, had
been denied by these reviews, and the
object of this statistical table is, to
prove by observation the incorrectness
of my second position—to show that it
was totally at variance with facts. I
shall now proceed to lay before you my
objections to it.

In order to this I shall first state the
physiological views upon which this
table has been constructed at the
Brittain Street Hospital. I shall next
give my reasons for considering such
views to be inadmissible; and then, by
comparing its results with those coming
from the observations of admitted au-
thority upon these subjects. I shall
show such a vast discrepancy between
them, that I think but little hesitation
will exist as to the extent of credit to
be attached to the testimony of this
document.

The table is based on the supposition
that the afterbirth moves with such
uniformity from its position *in utero* to
its birth and final deposition upon the
bed, that simply by inspecting this
latter (its position on the bed) we can
at once tell what part of the womb it
was attached to. In fact, that the
expelled placenta, as it lies on the bed,
observes a position so corresponding
with its former uterine attachment,
that, with very few exceptions indeed,
it may be regarded as an infallible
index thereto.

Before, however, we proceed to exa-

mine the merits of this doctrine, I have
to state, that it is now admitted the
fundus is not the position of the after-
birth, (I shall take leave to say—*at the
close of gestation*). It is found by exa-
mining the secundines, that its (*then?*)
place on the membranes, relatively to
the aperture in them made by the
escaping child, is somewhere in the
vicinity of the mouth of the womb:
there were but three exceptions to this
in the hundred cases recorded in this
table. The principle, then, upon which
the table is constructed we are informed
is, that the afterbirth, perpendicular,
or upon some of the sides of the womb
previous to its detachment, is so sepa-
rated therefrom, that its superior sec-
tion is detached momentarily earlier
than the inferior. That this superior
section is then thrown on the wall of
the womb opposite that from which it
has been just detached, the inferior
preserving its position. By this it is
said that the entire of it, when fully
detached, assumes a somewhat horizon-
tal or antero-posterior direction, in which
position it continues after, in its progress
through the pelvis and os externum,
and finally is deposited on the bed ob-
serving the same bearings. The mem-
branes, however, are firmly attached to
the fœtal surface of the placenta, at
least some of them; those, therefore,
which pass off from the lower border of
it must be short, inasmuch as they are
near the mouth of the womb, where the
opening is found in them as above
stated, while those which pass from the
superior border rise up, line so much of
the womb as is above the placenta, then
the fundus, and finally pass down lining
the opposite wall, unbroken, and must
be consequently long: in other words,
the long part of the membranes is on
the side of the womb opposite that to
which the placenta is attached; the
short part of them on the same side
with it.

Assuming, then, all these premises
as correct, the latter of which no doubt
is, we are now informed of their appli-
cation, in the way of discovering by
them the place in the uterus the pla-
centa was attached to. If, for example,
the placenta be on the posterior wall,
the superior part of it being first de-
tached and thrown on the anterior wall,
the inferior part continuing at the pos-
terior, it thus, as stated, assumes an
antero-posterior direction, and finally is

expelled in that exact position, the superior part, when lying on the bed, pointing towards the pubis, the posterior backwards towards the perineum. The consequence of this will be, that the longest part of the membranes will *then* have a pubal aspect, the shortest a perineal. The reverse of all this of course will happen when the placenta is on the anterior wall; the long part of the membranes will point backwards towards the perineum, the short part forwards towards the pubis: when on the sides, corresponding effects will follow. These preliminaries being all settled, we are told there is nothing easier than to ascertain, by them, where the placental attachment was in the womb: we have only to look where the long part of the membranes goes off from the mass as it lies on the bed; if that be from the pubal aspect, it lay on the back; if from the perineal, it was affixed anteriorly; and, as in a considerable number of the hundred submitted to this test at the Brittain-street Hospital, (we shall presently see 43.) we are informed they went off from the perineal: this is assumed as proof unquestionable, in the language of the review, "of how egregiously mistaken I was in my hypothesis that the placenta was to be found 96 or 97 times out of the 100 posteriorly attached." It is to be observed that the uterine position of it was, as we are informed, in all cases ascertained before the birth of the child by the stethoscope, and the correctness of the diagnosis verified afterwards by the above test in every individual instance, and it would appear without any exception whatever.

Against this doctrine, however, I beg leave shortly to submit the following objections:—First, although the earlier detachment of the superior portion of the placenta is stated in the critique as *quite obvious*, I by no means assent to this postulate. I have laid grounds in my paper for supposing, that uterine contraction is very much conducted on the anterior wall of the womb until the child is expelled; and if that be the case, I cannot see how such a mode of detachment is *so obvious ;* on the contrary, I should think the entire of the placento-uterine surface would be acted on at once: indeed, I think this must be so, no matter how the contractions be ; in which opinion I am strengthened by the well-known

fatal consequences resulting from partial detachment. But, admitting the superior portion to be first detached, by what means is *it* alone thrown to the opposite wall of the womb ? or why shall not the same thing occur to the inferior portion, when it in its turn comes likewise to be detached? Will not *this* then move to the opposite wall, or what is to prevent it ? Again, supposing all these granted, I contend the capacity of the womb is by no means such as to admit the advance of the superior section of the placenta to take place to such a degree as to permit the mass to assume the position necessary to sustain this argument. If we look to the table itself, we shall find the greater number of these placentæ measured seven inches in length. Let us now recollect that the thickness of the walls of the womb, anterior and posterior, after the child is born, is upwards of one inch each ; and we shall find that, in order to allow these seven-inch placentæ to assume the inclination contended for, particularly when we consider their soft pliant nature, that the diameter of the womb must, at least, be nine inches after the child is expelled. How mistaken, consequently, must all writers on midwifery be, who aver that the size of the womb then is about that of a fœtal head ! How different the doctrine at the Brittain Street Hospital. If such were the fact, the womb must diminish in no degree whatever by the expulsion of the child. It is also almost needless to remark, that when it continued in so patulous a condition, fatal hæmorrhage must have resulted in all cases, at least where the placenta measured seven inches. Of this no mention is made in the review ; but it is impossible it could be otherwise. One thing is very remarkable, connected with this table, that in upwards of thirty of the cases an hour and more elapsed before the placenta was expelled : in these certainly death from hæmorrhage must have happened a long time previous thereto, and, notwithstanding subsequent uterine action, went on so as to complete the evacuation of the secundines. This I should say was a strong exemplification of what I spoke of in my original paper on the subject, viz., that, even after death, the womb is sometimes known to act so as to expel the fœtus, were it not that here death

having ensued from hæmorrhage, its enervating effects must have been produced on, and so weakened the contractile tendency of, the uterine tissue.

The truth is, the placenta comes down from the womb edgewise, which a fact well known proves : I mean, when it is partly in the vagina, and partly in the womb, one half in either chamber, and which could not occur if it advanced in the antero-posterior or horizontal direction. When detached, its weight protrudes into the cyst of membranes, the womb acting on it from its substance and firmness before it acts on their delicate tissue ; it, consequently, advances, investing the membranes, and covered by them, and it is this which has been mistaken at Brittain Street for the advance of the fœtal surface.

With respect to the statement that it proceeds through and from the womb, preserving a position when fully expelled and lying on the bed, so unerringly corresponding to that of its uterine attachment, that by inspecting the former in the way mentioned we may at once learn the latter, a number of arguments at once present themselves to the mind against it : I shall, however, select but a few. The varied degrees of uterine action with which it is propelled to its birth, and, consequently, of the time that elapses previous to its completion, must I think affect this much. The well-known irregularity with which the womb now acts must likewise influence it very much. For example, suppose it were attached anteriorly or posteriorly ; if it were at once in all cases detached and expelled, some semblance of reason might probably then be attached to this doctrine ; but if after delivery it were not expelled for an hour or two (*see thirty of the cases in the table*) it must unquestionably gravitate to the side the patient lies upon (of the truth of this I have satisfied myself in numbers of instances,) and so mar the regularity necessary for the purpose. This must undoubtedly occur if the womb be so patulous and uncontracted as to admit of the reclining position contended for ; and how much the more will not this tendency to gravitate to that side be facilitated, by the bleeding which must ensue from such an uncontracted state of the organ. Again, we know that the placenta is the first

of the secundines to be expelled, the membranes coming after it ; these latter then restrain, in a degree, its advance, and so unequal at this time is the uterine action, that sometimes the restriction will be on one part of them, and sometimes on another ; thus permitting one time one portion of the placenta to be extruded, while another portion of it is confined, and sometimes another. Need I insist how this must affect the point under discussion ?   The part which is free being projected forwards, while that which is reined in as it were by the tense strip of the membrane, must be retained close to the person of the patient, thereby causing the position of the placenta on the bed to be influenced, not by that of its uterine attachment, but by whatever part of the membranes chance retained with the womb.   I believe we need not say more as to the physiology which constructed this table.   A few words on its workings.

I contend for it this is all wrong : the stethoscopic ear and seeing eye would appear to have verified each other.   As I differ from them, however, at Brittain Street, as regards the correctness of the evidence which it gives, the matter will best be decided by an umpire between us, and for that end I shall name Naegelé as a fit and proper person.

Now Naegelé directed his attention to the very matter under consideration, in six times the number of cases as those observed at Brittain Street—600 cases, (*see his obstetric auscultation*) and the results of his inquiries compared with those from the Dublin Hospital, exhibits this enormous discrepancy : while with him the placenta occurs in the average of but twice in the hundred on the anterior wall, the Brittain Street table makes it to exist *forty three times*. His remark is, that in the 600 cases " the placenta was found to occupy the anterior wall of the uterus, *in thirteen instances 'only.'*" Thus, in six hundred cases, the discrepancy between them would be in a proportion of 13 to 258 !!! I submit that such an enormous discrepancy could only be the result of a similar description of error on the part of either of these observers. The profession, however, will decide which was most likely to have fallen into this error.

But there is another matter which I

hold operates greatly against this table and is calculated to create much doubt as to its credibility. We have, I think, already seen that it proves too much for the purposes of the critique with respect to the frequency of the anterior position, which in my papers or thrice I contended for occurred but twice in the hundred; and I think we shall find that the stethoscope has been likewise quite too successful in it, rather incredibly so. Naegelé informs us in the work already cited, p. 80, that the souffle was so diffused and uncertain, in some of the cases he submitted to it, that it was *impossible* to determine the position of the placenta in them by the stethoscope ; and he further informs us that this impossibility occurred in a proportion of, *thirty* in the hundred, whereas it would appear that no such difficulty was by any means experienced at the Brittain Street Hospital. In not one instance did they fail there in foretelling its place by means of it, and so *infallible* was the ear *in all*, that it would appear the prognosis was subsequently verified by the test of the secundines, conducted on the principles above stated, in every individual instance Again, I would say, either observer must be very much in error as regards this, and, as I think, general opinion will bear to the side of Naegelé. I, from all these considerations, would submit that this table of statistics, which, we are informed, was "laid before the profession, in order to set all arguments at rest on this score, and to prove how egregiously mistaken I was in my hypothesis" (the very great unfrequency of the anterior position), has failed altogether in accomplishing this object. It occupies near eight pages of the *Dublin Journal of Medical Science.*

I have above stated that according to this table, the after-birth was found forty-three times in the hundred on the anterior wall. In the paragraph immediately succeeding it, in the *Dublin Journal,* it is stated as occurring there but twenty-five times ; however, we are likewise informed that in eighteen other instances it was below the Fallopian tubes to the right or left side. Now in . the body of the review, p. 32, it is said, " the Fallopian tubes are considerably in advance of the pregnant womb." This statement, no doubt, is quite wrong; they are very much posteriorly.

(See Hunter and Cloquet's plates.) However, such being the opinion at Brittain Street, it is clear that these eighteen were there considered in advance of the womb, not at the sides ; they must, therefore, be added to the above twenty-five, and thus the placenta would be in front of the womb in forty-three instances. Dewees is quoted as authority of the anterior portion of the tubes in advanced pregnancy, at p. 89 of his work. However, I believe this is also a mistake respecting him ; at least I could not find it.

The results of Naegelé's remarks were as follows, on the 600 cases :—

At the sides of the womb,	379	
Undeterminable	180	
At the fundus	7	
Anterior wall	13	*only.*
Over the os uteri	11	
Calcareous deposits . . .	10	
	600	

This account shews the greater number capable of being diagnosed by the stethoscope to have been laterally to the right or left side, which, at p. 78, Naegelé denominates " the ordinary position of the placenta," and which I submit, corresponds with the view I have taken of the subject. Naegelé says this position is in consequence of the vessels of the womb being greatest at the sides than elsewhere. I would, however, suggest as a reason for it, what I have already stated in my paper. The original formation of the placenta takes place at the orifice of the tube the ovum traversed, which is *then* at or near the fundus. At the full period of gestation, however, the tubes have sunk posteriorly and laterally about one-half on the uterine tumor (Hunter and Cloquet's plates). In this movement the attached placenta must of course participate, and thus it is that it is found there then. If that part of the womb be best supplied with blood, the effect of this change will be the more complete, as it will bring the full-grown placenta where it will be best supplied with it.

" I believe I may safely say that the *anterior* position of the placenta is a matter of the rarest occurrence ; for although it was found forty-three times in the one hundred, at the Dublin Brittain Hospital, or even twenty-five

times there affixed, Naegelé informs
us the average is but *twice* in the hun-
dred ; and his account, we may, I
think, adopt as the correct one.

Now I would contend for it, that
there must be some reason why nature
has in a measure excluded it from this
position, and also that of the fundus
(it was found by him, in the latter
position, but *once* in the hundred);
and I would submit that this is in con-
sequence of the expansion of the
womb taking place in the greatest de-
gree in these parts of it. Were the
afterbirth here attached, it is evident
that the growth of the two organs
would not correspond ; that of the
womb would exceed that of the pla-
centa, and disturbance of the function
of the latter must be inevitable, with
its consequences on the mother and
child ; but placed as it is, *laterally and
posteriorly*, it is on a part which in-
creases in a ratio that is adapted to the
placenta only, while the increase of the
anterior and fundal department is re-
served for that of the child.

I have stated in one of my papers on
this subject, that it is probable some of
those cases of abortion which take
place without any assignable cause,
may result from malposition anteriorly ;
and from some opportunities I have
had I am rather strengthened in this
opinion. The view I have taken of
this subject also leads to the inference
that there is some part of the womb
where alone the placenta can be safely
lodged, which the above testimony of
Naegelé, and the results of our inves-
tigations at the Coombe, I think goes
strongly to establish ; and I would
further say, that it may lead to facts
connected with the doctrine of acci-
dental hæmorrhage, so ably handled
by Rigby, which may throw much
light on the pathology of this affection.
The extensive opportunities afforded
for observation on these matters at the
Coombe Lying-in Hospital, have sug-
gested some reflections connected with
this latter, which I may take leave to
submit on another occasion.

In my paper I have suggested that
the posterior position of the tubes, ac-
companied by the placenta, at the close
of pregnancy, can only arise from the
anterior wall yielding more than the
other parts, and thus chiefly supplying
the expanding womb ; and which has
been explained in the notice lately

taken of it in this periodical, on the
supposition that the pressure of the
growing child anteriorly loosens out its
substance there, and so prepares it to
contribute readily to this expansion,
which obviously cannot take place in
other parts ; and the lateral position of
them I have accounted for, on the
grounds that the womb between them
enlarges just sufficient to accommodate
the increasing placenta. Such being
the case, the placenta attached at the
tube will extend upwards as much as
downwards, and backwards as much as
forwards, in its growth ; and thus,
though lateral, be likewise posterior,
and low on the womb at full time. I
have urged that its increase cannot
take place by all parts contributing
thereto, inasmuch as in that case the
fundus at the birth would be the fundus
of the first month, would rise up uni-
formly all through, and the placenta at
the former period be there found, which
it is not ; and I confess I am unable to
account for the change of position
which the tubes and the placenta un-
dergo, unless on the grounds just
stated.

In a future communication I shall
state how certain marks on the mem-
branes will enable us to ascertain the
information required on this point.

I am, sir,
Your obedient servant,
HUGH CARMICHAEL.

Dublin, Sept. 25, 1840.

CONSTIPATION CURED BY THE APPLICATION OF COLD.

To the Editor of the Medical Gazette.
SIR,

SHOULD you think the following case
sufficiently interesting, I should feel
obliged if you would insert it.
Your obedient servant,
J. WHITEHEAD.

Oxford Street, Manchester,
Sept. 29, 1840.

Mr. ——, of B. C. farm, is upwards of
60 years of age, and has in general
been in possession of good health, with
the exception of a little uneasiness now
and then arising from a constipated
state of the bowels, for the relief of
which he has occasionally taken senna
tea and Epsom salts. His bowels not
having acted for two or three days, he
took his usual dose of opening medi-

cine, which produced no other effect than severe griping. The medicine was several times repeated, and rejected as often ; the belly became tense and painful, and a feverish state of the system supervened. Medical advice was obtained towards the end of the fifth day, and the usual remedies prescribed; such as pills of calomel and colocynth, and a mixture containing sulphate of magnesia with infusion of senna and jalap : castor oil, croton oil, and several other powerful purgatives, were given, but without the desired effect. The belly was repeatedly leeched and fomented. Clysters containing castor oil were administered in large quantities, but without any beneficial result. Croton oil, turpentine, and tobacco, were all fairly tried, and produced no effect except sickness or syncope. There was no hernia. The abdomen greatly increased in size and tension ; the tenderness somewhat diminishing, and alarming symptoms of sinking manifested themselves, the pulse becoming small and feeble, the tongue dry, and the voice weak and tremulous. We were leaving the patient in this condition on the tenth day, when I suggested to my friend, who had charge of the case, that the application of cold water to the abdomen might prove of some service. We immediately returned to the house, and ordered that a bucket of cold water from under the ice (it was then the end of November, 1836) should be carried into the room. The old man feebly asked what we intended to do with him now, and was given to understand that the belly was to be fomented again. That the deception to him might be complete, a jug of boiling water was also ordered. The abdomen being fully exposed, and some of the bed-clothes carelessly thrown over his face, the ice-cold water was suddenly applied by means of a large roller towel, doubled up to the proper size. The shock, no doubt, was terrible enough. With all the energies that remained in him, the patient screamed out, " Oh dear ! you are killing me ! you are killing me !" Several towels were applied in succession in the same manner, at intervals of about a minute. The beneficial effect was almost instantaneous, for during the time that the first towel remained on the belly the tumefaction began to subside, and in four or five minutes became amaz-ingly reduced. The patient now expressed a wish to get out of bed, which he was assisted to do, and had a very copious evacuation of dry hard fæces, and two motions more before we left the house. By the aid of a little medicine the bowels were soon restored to their healthy condition, and the patient speedily recovered.

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Observations on the Diseases incident to Pregnancy and Childbed. By FLEET-WOOD CHURCHILL, M.D. &c. Dublin and London, 1840. 8vo. pp. 463.

ALTHOUGH most works on midwifery contain a brief survey of the nature and treatment of the diseases incident to pregnancy and childbed, the volume before us is by no means a useless addition to the medical catalogue. It contains a condensed and clear practical account of the diseases referred to, which the student and young practitioner cannot read without improvement ; while, at the same time, from the numerous references collected by the author to foreign and English authorities, he who is inclined to dip deeper into the various subjects which are discussed, will be saved the labour of personal research by referring to Dr. Churchill's foot-notes. The following are the contents of the work :—Diseases incident to pregnancy ; diseases of the genital organs in pregnant females ; disorders from sympathetic irritation ; disorders of the circulating, respiratory, and nervous systems : disorders of the mammæ ; disorders from mechanical pressure; diseases incident to child-bed. Upon all these subjects Dr. Churchill gives a great deal of very useful elementary information, which, as far as we know, will not be found in any other single work. He purposely adheres to matter-of-fact statements, and avoids the discussion of doubtful theories and speculations : hence the value of his work to students and young practitioners ; and to those who require information upon the various branches of obstetrics above enumerated, we can conscientiously recommend Dr. Churchill as a safe and useful guide.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

THE MEDICAL REFORM BILL.

WE have obtained a copy of the "Medical Profession Bill," prepared and brought in by Mr. Warburton, Mr. Wakley, and Mr. Hawes*. A very short account of it will at once suit best our present convenience, and convey to our readers all that can immediately interest them in its provisions. Its object is to add, if possible, another to the existing seventeen licensing bodies; and, of course, the hope is, that it may effect that which the London University has signally failed to do—the swamping of all the medical institutions that have the fault of being older than itself. We by no means regard our existing institutions as free from fault, and some of them, particularly the College of Physicians, we look upon as open to very grave objections,—but the reform must come from some wiser heads and more candid minds than those possessed by the honourable member for Bridport and his associates. Really, if it were not fraught with mischief, it would be very amusing to see legislators thus trying their hands at College-building; setting up one, and when that does not quite suit their purpose, laying the foundations of another on some more promising scheme; and talking of their patriotic economy, and their regard for science, all the time that they are burdening the country with the maintenance of their useless offspring, and rendering the profession

* What is the reason for which, though these three names are put on the back of the Bill, it is called in the Lancet of last week only Mr. *Warburton's* Medical Reform?

ridiculous by their perpetually changing schemes for its management.

The present is termed, " A bill for the registration of medical practitioners, and for establishing a College of medicine, and for enabling the fellows of that College to practise medicine in all or any of its branches, and hold any medical appointments whatsoever, in any part whatsoever of the United Kingdom." It is fairly divisible into two parts, relating respectively to the registration, which it is proposed to make compulsory on all medical practitioners, of whatever kind or dignity of diploma, and to the establishment of the new College, in which those only who are inclined to take part in the election of its officers need have any interest. With reference to the first of these objects, it is (if possible) to be enacted that, after 1842, a "medical registrar" is to be appointed in each of the three capitals of the kingdom, to whom the present registrars of births and deaths (who will thus enjoy the well-associated and comprehensive function of supervising all the births, deaths, and doctors), are to act as sub-registrars. Through the medium of these latter, every practitioner will furnish each year to the chief registrar a schedule of his name and domicile, the branch of the profession in which he practises, and nature and dates of his qualification, to be signed and returned on or before the 31st of March.

In return for the trouble of making these "Medical Practitioners' Returns," every practitioner is to be annually taxed, to an extent not mentioned, for the maintenance of Mr. Warburton's faculty, and for the formation of a Medical Registry Account, for the improvement of medical education. The registers of licensed practitioners are to be printed and published every year. They will thus form a useful list of all the practitioners

throughout the kingdom, and of the qualifications of each, which it will undoubtedly be advantageous to possess for many other purposes than that which is contemplated in the bill, namely, the election of the officers of the new faculty.

But in addition to the register of qualified or licensed medical practitioners, there will also be one of those who practise medicine in their capacity of chemists and druggists, or who practise it without having even that evidence of their fitness ; and this register it will be left to the Home Secretary of State to publish or keep secret, as he may think fit. It will be seen by this that countenance is in future to be given to all who choose to practise medicine, however complete their want of fitness may be ; and although in subsequent clauses it is to be enacted that only those who are qualified to practise by some license or diploma shall hold any public or parochial medical appointment, or charge for their professional attendance, yet there is not proposed any means whatever of discouraging the vast number of self-constituted practitioners (chemists, quacks, and others,) who at once disgrace the respectability, and diminish the pecuniary profits, of the legalized members of the profession. On the contrary, a certain amount of encouragement is given to them, by their being distinctly recognized as practitioners, although placed in a separate class. Whatever may be thought of the other provisions of the bill, this cannot fail, we imagine, to meet with general disapprobation : if there be one point on which all the members of the profession are agreed, it is that their diplomas, by whatever faculty or corporation they are granted, should, in addition to the honour they confer, have some actual advantages ; but, were the present bill passed, quacks would be more nearly than

ever placed on an equality with the authorized practitioners as well of the new as of the older faculties.

The registration, we have said, is to be compulsory. After July in some unknown year, no unregistered person, even though diplomatized or licensed by any existing body, will be allowed to act as a medical practitioner in any part of the united kingdom.

The register of qualified practitioners, in addition to the value we have admitted it will have as a list and description of all the legalized members of the profession in the kingdom, is also intended to serve the less important purpose of a list of the electors qualified to vote for two-thirds of the members of the councils of the new college : and here we enter upon the second part of the bill. Its scheme might be briefly described as that of an experiment to see whether a system of general election can be worked, and is sufficiently desired by the members of the profession, to induce a great number of them to join voluntarily an institution which will confer no privileges on them beyond that of choosing some of those who are to hold office. This experiment is to be thus conducted : three councils, each composed of 36 members, are to be formed in England, Ireland, and Scotland ; of the 36, 12 are to be nonmedical men APPOINTED by the Secretary of State, and 24 are to be ELECTED by the qualified and registered electors from among themselves, by means of secret voting papers sent to them by the registrars, and returned through the sub-registrars to the registrars, and to scrutineers elected in the same manner by the electors. Of the 12 laymen, the Secretary of State will cause three to vacate their offices annually, and will replace them by others. Of the 24 medical members of each council, the electors will in each year vote out six in nearly the same way as they voted

MEDICAL GAZETTE.

THE MEDICAL REFORM BILL.

WE have obtained a copy of the " Medi-
cal Profession Bill," prepared and
brought in by Mr. Warburton, Mr.
Wakley, and Mr. Hawes*. A very short
account of it will at once suit best
our present convenience, and convey
to our readers all that can immediately
interest them in its provisions.   Its
object is to add, if possible, another to
the existing seventeen licensing bodies ;
and, of course, the hope is, that it may
effect that which the London University
has signally failed to do—the swamping
of all the medical institutions that have
the fault of being older than itself.
We by no means regard our existing
institutions as free from fault, and
some of them, particularly the College
of Physicians, we look upon as open
to very grave objections,—but the re-
form must come from some wiser heads
and more candid minds than those
possessed by the honourable member
for Bridport and his associates. Really,
if it were not fraught with mischief,
it would be very amusing to see legis-
lators thus trying their hands at College-
building ; setting up one, and when
that does not quite suit their purpose,
laying the foundations of another on
some more promising scheme ; and
talking of their patriotic economy, and
their regard for science, all the time
that they are burdening the country
with the maintenance of their useless
offspring, and rendering the profession

* What is the reason for which, though these
three names are put on the back of the Bill, it
is called in the Lancet of last week only Mr.
Warburton's Medical Reform ?

ridiculous by their perpetually changing
schemes for its management.

The present is termed, " A bill for
the registration of medical practitioners,
and for establishing a College of medi-
cine, and for enabling the fellows of
that College to practise medicine in all
or any of its branches, and hold any
medical appointments whatsoever, in
any part whatsoever of the United
Kingdom." It is fairly divisible into
two parts, relating respectively to the
registration, which it is proposed to
make compulsory on all medical prac-
titioners, of whatever kind or dignity
of diploma, and to the establishment of
the new College, in which those only
who are inclined to take part in the
election of its officers need have any
interest. With reference to the first of
these objects, it is (if possible) to be
enacted that, after 1842, a " medical
registrar" is to be appointed in each
of the three capitals of the kingdom,
to whom the present registrars of births
and deaths (who will thus enjoy the
well - associated and comprehensive
function of supervising all the births,
deaths, and doctors), are to act as sub-
registrars. Through the medium of these
latter, every practitioner will furnish
each year to the chief registrar a sche-
dule of his name and domicile, the
branch of the profession in which he
practises, and nature and dates of his
qualification, to be signed and returned
on or before the 31st of March.

In return for the trouble of making
these "Medical Practitioners' Returns,"
every practitioner is to be annually
taxed, to an extent not mentioned, for
the maintenance of Mr. Warbuton's
faculty, and for the formation of a
Medical Registry Account, for the im-
provement of medical education. The
registers of licensed practitioners are
to be printed and published every
year.   They will thus form a use-
ful   list   of   all   the   practitioners

throughout the kingdom, and of the qualifications of each, which it will undoubtedly be advantageous to possess for many other purposes than that which is contemplated in the bill, namely, the election of the officers of the new faculty.

But in addition to the register of qualified or licensed medical practitioners, there will also be one of those who practise medicine in their capacity of chemists and druggists, or who practise it without having even that evidence of their fitness ; and this register it will be left to the Home Secretary of State to publish or keep secret, as he may think fit. It will be seen by this that countenance is in future to be given to all who choose to practise medicine, however complete their want of fitness may be ; and although in subsequent clauses it is to be enacted that only those who are qualified to practise by some license or diploma shall hold any public or parochial medical appointment, or charge for their professional attendance, yet there is not proposed any means whatever of discouraging the vast number of self-constituted practitioners (chemists, quacks, and others,) who at once disgrace the respectability, and diminish the pecuniary profits, of the legalized members of the profession. On the contrary, a certain amount of encouragement is given to them, by their being distinctly recognized as practitioners, although placed in a separate class. Whatever may be thought of the other provisions of the bill, this cannot fail, we imagine, to meet with general disapprobation : if there be one point on which all the members of the profession are agreed, it is that their diplomas, by whatever faculty or corporation they are granted, should, in addition to the honour they confer, have some actual advantages ; but, were the present bill passed, quacks would be more nearly than

ever placed on an equality with the authorized practitioners as well of the new as of the older faculties.

The registration, we have said, is to be compulsory. After July in some unknown year, no unregistered person, even though diplomatized or licensed by any existing body, will be allowed to act as a medical practitioner in any part of the united kingdom.

The register of qualified practitioners, in addition to the value we have admitted it will have as a list and description of all the legalized members of the profession in the kingdom, is also intended to serve the less important purpose of a list of the electors qualified to vote for two-thirds of the members of the councils of the new college : and here we enter upon the second part of the bill. Its scheme might be briefly described as that of an experiment to see whether a system of general election can be worked, and is sufficiently desired by the members of the profession, to induce a great number of them to join voluntarily an institution which will confer no privileges on them beyond that of choosing some of those who are to hold office. This experiment is to be thus conducted : three councils, each composed of 36 members, are to be formed in England, Ireland, and Scotland ; of the 36, 12 are to be non-medical men APPOINTED by the Secretary of State, and 24 are to be ELECTED by the qualified and registered electors from among themselves, by means of secret voting papers sent to them by the registrars, and returned through the sub-registrars to the registrars, and to scrutineers elected in the same manner by the electors. Of the 12 laymen, the Secretary of State will cause three to vacate their offices annually, and will replace them by others. Of the 24 medical members of each council, the electors will in each year vote out six in nearly the same way as they voted

them in, and replace them by six others; but on these proceedings the council will offer recommendations which may or may not be attended to, as the electors may think proper. From each of the three metropolitan councils of 36, four *appointed* and eight *elected* members are to be annually chosen, and these 36 doubly-distilled are to constitute a *medical senate*, who are to meet in October in each year in London, but must all vacate their seats in the following year. This senate is to have power to make bye-laws, binding on the councils, on all fellows of the future colleges, and on all beneath them. The councils also may make regulations, subject to the approval of the senate, for carrying into effect the intentions of the latter.

In the next stage of the experiment, a " College of Medicine of the United Kingdom" is to be founded, whose fellows are to consist of all the medical councillors elected in the first and subsequent years of its existence, (all of whom will be fellows for life, although they may cease to be members of the councils), and also of such other qualified and registered practitioners as the senate may pronounce to be eligible without examination, and as the councils will elect by ballot. One of the first duties of the senate will be to define who of the present race of qualified practitioners may claim to be fellows of the College without undergoing any examination. The senate is also to determine the nature and methods of the examinations, on passing which, persons, not already in medical practice, may be admitted as matriculated students of the said College; the course of instruction, the registration, &c., which they are to undergo during the period of their studentship, and the nature and modes of the examinations which, at the conclusion of their studies, they must pass,

in order to obtain the fellowship of the College. The examiners both for the matriculation and for the fellowship are to be appointed by the councils, but not from among their non-members. The fellows of the College are to be licensed to practise as surgeon-apothecaries, or general practitioners of medicine, in any part whatsoever of the British dominions, and to enjoy in any of them all the advantages of all kinds to which surgeons or apothecaries have been hitherto entitled.

This will be the consummation of the main part of the new scheme; a few less important particulars follow, but we must reserve these for another occasion. It will be sufficiently evident already that this is not a plan for amalgamating professional differences, or correcting any errors, but merely a scheme for an eighteenth faculty. The name and plan of the senate—the powers given to it in respect of the examination of candidates, and the appointment of courses of study, are on the model of those granted to the London University. Now there is surely not a legislator, except the immediate framers of the bill, who will not ask, what is to be done with the institution so lately established on what were deemed the most popular principles, supported as it was by those very persons who are now pressing forward another, which, if successful, must utterly swamp it? Is it not truly extravagant that the scheme of one new institution should be barely completed, —that it should have scarcely had one year's trial or grace, before it is proposed by those who were among the most active in promoting it to overwhelm their own project by means of another which, in its least exceptionable parts, closely resembles it, and has no one character in which it excels its prototype? We must say, that low as our estimation has been of Mr.

Warburton, and the other parties concerned, we did not expect any thing at once so unnecessary, so preposterous, and so absurd.

BRITISH ASSOCIATION.
Tuesday, September 22d.
SECTION E.—MEDICAL SCIENCE.

Dr. Watson in the Chair.

Dr. Charles W. Bell read a paper on Bronten d'Altepe, and Baghdad, in the East.

Dr. J. R. Cormack read a communication on air in the veins. He stated that his object in bringing the subject at all before the Section was, humbly to state what appeared to him a sufficient objection to the theory lately published by Sir C. Bell. He would not recapitulate details which he had already submitted to the profession at some length. Sir C. Bell believes that death is produced by the air acting detrimentally on the medulla oblongata — that is, on the respiratory column of it. Dr. C. had slowly injected large quantities of air into the veins of animals, without causing death ; and, indeed, unless much air *was quickly thrown in,* the animal did not die. Dr. C. farther stated, that in every case in which the experiment proved fatal, the right side of the heart was found enormously distended, and unable to contract, and he preferred considering this obvious and constantly to be observed lesion as the cause of death, rather than any thing founded on hypothesis, however ingeniously that hypothesis might be defended.

Dr. J. Reid believed that the views of Dr. Cormack were correct, and had seen many of the experiments referred to.

Dr. Pagan, of Glasgow, wished to know if Dr. C. thought that, in cases of traumatic gangrene, the air evolved might not prove fatal in the manner alluded to ?

Dr. Cormack.— In some cases it may. But it would require a large quantity of air, and that suddenly evolved, to cause death in the manner described. I have discussed this question in the last chapter of my thesis. Dr. Cormack then read some medical notes regarding Tangier, in Barbary, which he had lately visited.

Dr. John Reid read a valuable paper on the Anatomy of the Medulla Oblongata. The object of this communication was to point out the relative position of the motor and sensitive columns of the spinal cord, as they pass through the medulla oblongata and pons varolii, and describe the attachment of the different motor and sensiferous nerves to these columns. Dr. Reid exhibited dissections, from which it appeared that the decussation of the pyramidal bodies is formed by the greater part, and in some cases by the whole of the fibres constituting these two eminences decussating with each other, and then passing into the posterior part of the middle column. None of these decussating fibres run into the anterior column of the opposite side, and there is no other decussation in the medulla oblongata besides this. On tracing the column which is connected with the olivary body, and which may be called the olivary column, we find that it passes downwards, approaches closely to the anterior medium fissure, immediately below the decussation of the pyramidal columns, and affords attachment to many of the roots of the motor nerves. On tracing this olivary column upwards, it is found to expand over the olivary body, affording origin to the hypoglossal and abducens along its anterior margin, and to the portio dura along its posterior margin. Part of this olivary column passes upwards to the corpora quadrigemina, affording origin to the smaller root of the fifth, and to the trochleator nerve. Dr. Reid also pointed out how the spinal accessory and part of the filaments of the par vagum may be connected with the motor column.

The president stated that the Association had voted £200 to bring over Alexis from America, and he trusted that his visit to the place of meeting next year would throw some light on a dark subject in physiology.

Dr. Allen Thompson then gave an account of the anatomy of the intestinal glands, illustrated by a great many diagrams and preparations.

Dr. Perry read a valuable paper on inflammation, and gave a tabular view of 152 post-mortem inspections made in a continued series, and all under his own eye.

Dr. Hannay, of the Andersonian University, read a memoir on hooping cough, in which he recommended cold washing to the chest. He had also found it useful in laryngismus stridulus.

The Secretary read an elaborate paper, by Dr. William Macdonald, on mnemonics, which seemed an attempt to classify mental diseases under three heads.

[On the 21st a valuable paper, from which we shall make some extracts, was read by Dr. Cowan, on the vital statistics of Glasgow. A report on the action of the heart was also presented, which has been transmitted to us, and which we shall give at length.]

ON WILDBAD IN THE KINGDOM OF WURTEMBERG.

By. Dr. Fallati.

The most comprehensive category under which to include patients who are sure to be relieved, if not cured, at Wildbad, is that of persons who are suffering from gouty dycerasia, or a rheumatic diathesis. I have seen all diseases grow better at Wildbad, which belonged to this class, and were likely to be benefited by warm baths, whatever might be the system or organ in which they made their appearance ; and among them were cases in which this could hardly have been expected. This character of disease was the cause of the success of the treatment in a great number of cases of paralysis, and anchylosis, as well as of some cases of hemorrhoidal, calculous, and other urinary disorders.

It is remarkable that, in particular, local diseases, which either consist of a swelling caused by some morbid deposit, or in which such a deposit, though not visible, may be supposed, decrease rapidly and surprisingly, even when they do not depend on a gouty or rheumatic diathesis.

The baths of Wildbad appear to increase the absorption of morbid deposits more than I could have believed, had I not seen it in my own experience. As exudations of this kind occur in arthritic or rheumatic subjects from internal causes, so they occur in persons otherwise healthy from external injuries, particularly about the joints ; and it is for the cure of these surgical cases that Wildbad has always been celebrated. It is the same with the different diseases of the bones depending on such causes, together with abscess, fistula, and stiffness in the neighbouring soft parts remaining after fracture. When the patients are young, and can bear the bath, such cases often form the most brilliant cures.

Those cases of paralysis and paresis which have arisen from any pressure on the corresponding part of the nervous system, whether by extravasation or exudation, are proportionably more easy of cure than others. Yet I have seen marked improvement even in those which arose from a dynamic cause, namely, fright. I particularly recollect the cure of a boy, who, in consequence of spasms in one leg resembling chorea, had lost all strength in it. He had partly recovered its use under the care of Dr. Chelius at Heidelberg, who completed his cure by prescribing Wildbad.

I have found its effects on the organs of reproduction and their functions, particularly in women, such as might have been expected from the properties of the water. In men also I have found that too frequent pollutions, arising from an excessive irritability of the genitals, gave way and became normal ; while in a case of incipient paralysis, of the lower extremities particularly, emission, which had been absent for months, returned after the use of the baths.

In conclusion, I have to make a remark which speaks as much for the efficacy of Wildbad as its powers in curing disease does. I mean its injurious influence on the healthy. This influence is perceived after a few baths of short duration, or a single bath of long duration, especially in young persons who are plethoric, and inclined to congestions. In one case the symptoms threatened apoplexy ; in others a simple but active vascular fever came on, which was accompanied by oppressive headache, lasted for weeks, and was resolved by perspiration. In some persons the local application of our springs, as a hip or foot-bath, has caused a sensation of warmth in the skin, lasting more than twelve hours, and was like that which follows a sinapism, without producing redness of the skin. The patients asserted that they had not remarked it after local baths of common water at the same temperature, nor even after the use of entire baths of the Wildbad springs. The reason of this may have been, at least in the latter case, that a point of comparison, furnished by the unmoistened part of the skin, was wanting.

The season at Wildbad begins on the 15th of May.—*Zeitschrift für die gesammte Medicin*, May, 1840.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, August 14, 1840.

William M'Mahon.—Anthony F. C. Colclough. —Turner O'Langlin.—Charles Basley. — John Cornwall. - James Coghlan.—John H. Rowland. —John George.—Wm. B. Egan.

Prevailing wind S.W.

On the 23d generally clear, rain at times ; the 24th cloudy, with frequent showers of rain ; the 25th morning cloudy, with small rain, otherwise clear ; the 26th morning clear, afternoon and evening cloudy, with rain ; the 27th generally clear, raining during the night ; the 28th cloudy, rain falling nearly all the day ; the 29th generally clear, rain at times.

Rain fallen, one inch and ·165 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture III.

Softening; its causes and varieties—Transformations of Tissue; laws of their occurrence — Transformation into Cartilage, Skin, Fibrous Tissue, Synovial Membrane, Adipous Tissue, Mucous Tissue, Bone. New Tissues. Changes of situation—in the Chest, of the Lung, of the Heart — in the Abdomen and Pelvis, Hernia, Intussusception, Prolapsus.

Softening.—We were occupied with that branch of pathological enquiry which relates to the various ways in which the several parts and organs of the living body are liable to be altered by disease.

We considered the changes to which the solid parts are subject in *bulk* and *form*; and that alteration of their consistence which constitutes hardening or *induration*.

The opposite condition to this is *softening*, diminished consistence, a less degree of cohesion of parts and tissues than is natural.

This also is a state of which it is important that you should comprehend the nature, and causes, and varieties; and the share that it often has in breaking down the structure of organs, and in destroying life.

There is scarcely any tissue of the living body in which softening may not take place. I shall here, however, as before, mention a few illustrations only of its occurrence, taking those instances in which the phenomenon is most evident, or is best understood.

Softening is perhaps never more strikingly obvious to our senses than when it affects the brain or spinal cord. We find portions

671.—XXVII.

of these organs manifestly softer than the rest. You are familiar with the usual consistence of the adult brain: you will find it sometimes reduced, in places, to the consistence of cream: a gentle stream of water suffered to fall upon the softened pulp suffices to wash it away, and a cavity is left in its place.

The cellular tissue is another part in which softening is exceedingly common, although the change is not so readily perceived. The cellular tissue is the great connecting tissue of the body; and we are made sensible of its diminished consistence when parts which it unites become separable with unusual ease. Thus you may sometimes, by exerting a very slight degree of force, strip off a serous membrane from the parts that it invests, or a mucous membrane from the surface lined by it. This ready separation is a consequence of the diminished consistence of the subserous, or the submucous, cellular tissue. The membranes themselves, in such cases, may be in a perfectly natural state.

Muscles, again, are often palpably softer than they should be: the muscular substance of the heart, for example. Here the muscular fibre may itself have undergone a change of consistence; or the muscle may simply appear to be softened, in consequence of the softening of the threads of cellular tissue by which its fibres are tied together.

The mucous membranes very frequently present the phenomenon of softening. This is more commonly seen in the stomach than elsewhere. Instead of being raised from the subjacent tissues in large flakes, the mucous membrane, when seized between the forceps, breaks off in small fragments, or it may be crushed and mashed by the pressure of the finger, or washed away in shapeless pulp by a little current of water. This condition of its lining membrane is usually limited to parts of the stomach; but occasionally it is general.

Even the bones are liable to this change

F

of consistence. There is a disease called *mollities ossium*, in which the bones even of adults become soft and pliant, and capable of bending in any direction. There is a deficiency in their earthy constituents ; atrophy of that particular tissue. Indeed, softening is often a concomitant of atrophy.

The accidental products to which I adverted when speaking of induration — especially some of the forms of carcinoma — are sometimes remarkably soft, resembling brain in consistence and appearance, or cream, or jelly. But in these cases we can scarcely consider the change as an example of softening of the textures of the body ; it rather consists in the addition of parts that are themselves soft and half fluid.

Now softening may occur under very different circumstances. One very general cause of softening is inflammation. Every part, I believe, that is inflamed, undergoes, in the first instance, a diminution of its consistence. This appears to be almost the necessary consequence of the stagnation of the blood, the effusion of serosity, and the suspension of healthy nutrition. These are circumstances to which I shall recur. I cannot avoid alluding occasionally to things with which you are supposed to be as yet but little acquainted, and which will engage our particular attention as the course advances.

It would be a great mistake, however, to suppose that all softening results from previous inflammation. Doubtless it often proceeds from the direct and simple diminution of nutrition, and is then closely allied, as I said before, to atrophy. Thus softening of the brain is, sometimes, due to inflammation : we meet with it where the inflammation has been unequivocal, and has been caused by external injury ; but sometimes also it is quite independent of inflammation, and is owing to disease of the cerebral arteries, whereby the brain, or a portion of it, is deprived of its full supply of arterial blood, and ceases to be properly renovated : hence a loosening of its texture — a separation of its component particles — an approach to the fluid state. I shall, of course, hereafter endeavour to point out to you more particularly the means we possess of distinguishing these two forms of cerebral softening ; they constitute morbid conditions of the highest interest.

I may observe, that we have an illustration of the principle now laid down, in that general softness, flaccidity, and slight cohesion of parts, noticeable in children, or others, who are imperfectly nourished. We find this general absence of the natural firmness coincident with paleness, and a thin watery condition of the blood. Magendie kept animals upon food unsuitable to them, containing no azote, and incapable of sup-

plying sufficient nourishment ; and one curious consequence that followed was a loss of substance in the cornea, which melted down and disappeared.

There is another source of softening which requires to be mentioned — I mean the gastric juice, which has the power of dissolving not only food which is submitted to its action, but the mucous membrane of the stomach itself, and even all its tissues and coats. This cause of softening operates, however, in the dead body only ; but its effects have often been mistaken for the consequences of disease ; and therefore it will be necessary for me hereafter to call your attention to the circumstances under which they may be expected, and to the means we possess of discriminating them from similar changes, which are more properly called morbid.

Upon the whole, it may be said that every form and kind of softening in the living body — whether it proceed from inflammation, from disease of the arteries, from insufficient sustenance, or from altered qualities of the blood — may ultimately be resolved into suspended or defective nutrition.

Furthermore, as there is a hardness of parts resulting from repletion and distension, so there is a *softness* rather than a *softening*, from their emptiness and flaccidity : as of the breast immediately after the child has sucked — of the integuments in those who, having been fat, have wasted, either from disease or from advancing age, and so on.

Transformations of tissue. — There are a curious set of changes in the living body constituting, or arising from, what has been called, by modern pathologists, the *transformation* of tissues. In the proper place of one natural tissue we sometimes find another, which last is thus *un*natural in regard to its situation, but natural in all other respects. The new tissue is such as we meet with elsewhere in the body, but it is not such as properly belongs to the place it occupies. Either the original tissue has been gradually converted into the new, or the original tissue has disappeared, and the new tissue has been substituted for it ; that, for example, which should be cartilage we sometimes find to be bone, or *rice versâ*. The new tissue may not be, and perhaps seldom is, so perfect as that which is natural, but it very closely approximates to it in sensible qualities and physical structure.

This mode of alteration, incidental to parts of the body, has not been much attended to till of late years ; yet it is peculiarly interesting, inasmuch as some of the laws, according to which the transformations take place, seem to have been satisfactorily ascertained.

In most cases the tissue that has been changed or displaced is in one of the two following predicaments : —

Either its natural function has been for a long time suspended;

Or, it has been accidentally called upon to fulfil a purpose for which it was not originally destined.

In the former case, it gradually approximates towards cellular tissue, and is at length converted into it.

In the latter, it assumes the characters of that other tissue, of which it has taken up the office.

Now all this is curiously in accordance with what we know of the laws that govern the progressive development of the human body. In the embryo, all the tissues commence by being cellular tissue, and they only assume other forms and characters, each on the condition (so to speak) of its fulfilling some special purpose. Certain of the embryonic tissues do not attain their ultimate and perfect state until they have passed through the forms of two or three other tissues in succession. This being so, we can the more easily understand how there should be a tendency in each tissue to revert to its primitive state – to the state, *i. e.* of cellular tissue – when the exercise of its peculiar function ceases. The law coincides with that by which the hypertrophy and atrophy of parts are governed, these changes being but plus and minus degrees of the same process. A muscle, put for a long time in a state of complete inaction, gradually passes from the muscular into adipous tissue, and at length into cellular.

Again, if the nature of the original function determines in the first instance the nature of the tissue, we have the less difficulty in conceiving how the nature of a new and accidental function imposed upon a tissue may determine the kind of transformation it shall suffer. Thus, to take again the instance of muscle, if a muscle comes accidentally to lie round and invest an unreduced joint after a dislocation, it assumes the characters, together with the uses, of those tissues which naturally enclose the joint—it is converted into fibrous or ligamentous tissue. We find the very same law prevailing in the vegetable kingdom: the cut *branch* of a willow tree, for example, planted in the earth, takes up the office, and gradually acquires the form and properties of a *root*.

You are not to suppose however that this transformation of tissues is indiscriminate; while all tissues are convertible into tissues different from themselves, there is a limit to the number into which they can be transformed. Nerve, muscle, and gland, are convertible into other tissues, but other tissues are not converted into them. The cellular tissue being the original web upon which all the natural tissues are constructed, is accordingly capable of numerous transformations. The other

tissues admit of one, or two, or three forms only of conversion. There are some transformations much more common also than others; the change, for example, into adipous tissue, and into osseous tissue.

Not only do conversions of tissue take place during the growth of the fœtus, but the several tissues (as we learn from the study of comparative anatomy) are substituted, the one for the other, in different species of adult animals, according to the needs of these creatures; what is cartilaginous or fibrous tissue in one animal, is bone, perhaps, in another. For example, the *fibrous* sclerotic of quadrupeds becomes *bony* in fishes.

Now the following laws on this subject have been stated by Andral:—

1. Those tissues alone in the human body are susceptible of morbid or accidental transformation, which, in the progress of uterine life, or in the ascending series of adult animals, undergo regular or normal transformations. In this category are included the muscular, fibrous, cartilaginous, mucous, and cutaneous tissues.

2. The accidental transformations to which these tissues are liable are of the same kind with the normal transformations that occur in the fœtus, or in the scale of adult animals. For instance, cartilage may be converted into bone, but it is never changed into the mucous tissue.

3. Those tissues which in the embryo, or in the ascending series of animals, undergo no known transformation, undergo none of these morbid conversions. If they ever appear to do so, it is, in truth, from the conversion of parts immediately contiguous to them.

4. Every tissue that becomes atrophied tends towards a conversion into cellular tissue; retrogrades, as it were, towards its primitive organization.

In strictness of language this change ought not perhaps to be called a *transformation:* the proper substance of the tissue or organ vanishes, and the cellular tissue that sustained it being left behind, becomes more apparent.

These transformations then are not the offspring of mere chance, but obey laws originally impressed upon the living body, and impressed for wise and benevolent ends. They exemplify the working of what the older pathologists discerned, and called the *vis medicatrix naturæ.* This is a phrase that has been much sneered at; but (as I conceive) very unjustly, and sometimes ignorantly. It is simply a short formulary expressive of a great general truth, viz., that the animal frame is so constituted that, while it is necessarily liable to injury and disorder, it contains within itself the ele-

ments of repair, and of conservative adaptation. To a certain extent it is a *self-mending* machine. Surely this is an admirable provision, and strongly indicative both of wise design and of beneficent intention.

Special transformations take place then, when a tissue falls into disuse, or when a new function devolves upon it. But may all transformations be included within these limits ? What is called ossification of the coats of an artery is of very frequent occurrence. Here there is neither any cessation of natural function, nor any assumption of a new function. The same may be said of ossification of the cartilages of the ribs, and of the larynx. It would seem, therefore, that there must be other agencies or conditions under which the transformation of tissues is brought about. One of the circumstances assigned as an occasional cause of such changes is what is rather vaguely called irritation. It is said, for example, that chronic inflammation and ulceration of the mucous membrane of the larynx favours and accelerates the conversion of the laryngeal cartilages into bone. A joint that becomes ankylosed under slow inflammation is a case still more in point. Another circumstance which certainly has some connexion with the same change is age. In old persons we find, almost always, more or less ossification of the cartilaginous tissue in various parts of the body.

It has been urged, by those who desire to establish the universality of the rules now laid down, that the cases adduced as exceptions to those rules are not cases of true transformation, but of morbid deposit. The earthy patches which constitute the ossification of arteries differ from bone in their chemical composition — are sometimes very small and scattered—while the intervening parts of the tissue in which they are found remain quite healthy. These circumstances, they argue, distinguish such changes from real conversions of tissue.

Bearing in mind what has already been said, let us briefly run over a few of the most common and remarkable transformations presented to us in the human body.

Cartilage.—Of the conversion of cellular or other tissues into *cartilage* we have every-day instances in the parietes of arteries—in the valves of the heart—in the walls of morbid cysts—sometimes even in the walls of a vomica.

Of transformations into cutaneous tissue, or *skin*, by far the best examples we have are furnished by the mucous membranes. When a portion of the mucous membrane of the rectum, for instance, or of the vagina, protrudes externally, is permanently exposed to the air, and subject to the friction of clothes, or of neighbouring parts—that is to say, when it is placed under the same conditions with the skin—it assumes the characters of the skin : it gradually loses its red colour and approaches the tint of the skin, ceases to secrete mucus, becomes dry, obtains even a permanent cuticle, acquires firmness and density, and is less sensible to the contact and pressure of foreign substances. It is impossible not to perceive the beneficial nature of this transformation.

Fibrous tissue and synovial membrane.— A new formation of *fibrous* tissue may result from the conversion of cellular tissue, or of cartilage, or of synovial membrane, or of muscle. I have already spoken of this change as it is seen in unreduced dislocations : it is common wherever false joints are formed. And almost under the same head we may place the conversion of cellular tissue into *synovial* membrane. Synovial membrane seems, indeed, to be little more than condensed cellular tissue. Sir B. Brodie, in his book on Diseases of the Joints, gives instances of synovial membranes being formed, where none before existed. " In a young lady who had attained the age of ten or twelve years, labouring under the inconvenience of a club-foot, a large bursa was distinctly to be felt on that part of the instep which came in contact with the ground in walking. In another young lady, who had apparently recovered of a caries of the spine, attended with a considerable angular curvature, a bursa appeared to have been formed between the projecting spinous process and the skin."

We cannot look upon any of the last mentioned changes as being morbid : they are clearly the result of natural and spontaneous methods of cure, or of accommodation.

The conversion of other tissues into *adipous tissue*, or fat, is a very curious and a very common change. Generally, I believe, this occurs in connexion with suspended function. Sometimes there is an apparent transformation of this kind in cases of hypertrophy of the adipous tissue, or general obesity, such as I have previously described. But probably these are not true transformations. If you examine a fat heart—such as is not uncommonly met with in very fat persons—you will generally find a combination of hypertrophy of the adipous tissue with atrophy of the muscular, rather than any conversion of the one into the other. The fat is deposited around, or even between the wasted muscular fibres, and the two may usually be separated from each other. It would seem, therefore, that here the converse of one of the propositions which I lately mentioned holds good—of the proposition, namely, that a suspension of the function of a tissue leads to its degeneration into adipous or cellular tissue : in the

instance before us, the accumulation of adipous tissue tends to diminish, or at length to abolish, the function of the part.

Dr. Carswell, however, believes that a real conversion of the muscular tissue into the adipous takes place : and he states that the change is most conspicuous in the muscles of the lower extremities, when the limb has long remained motionless through palsy. The muscular fibres remain distinct, but are of a pale white, or straw colour, and when they are pressed between the fingers a clear oily fluid oozes out. If a portion of the muscle be steeped for a time in alcohol, this oil collects, in considerable quantity, on the surface of the spirit. What is called the fatty liver affords an instance of a morbid conversion, not at all unfrequent. The altered liver is of a light tawny colour, of diminished specific gravity, retains the impression of one's finger, is tender, and tears easily : it greases the knife that cuts it, or bibulous paper in which it is wrapped. By boiling it you may obtain a concrete oil, which has all the characters of fat.

Now what is very curious in respect to this morbid condition of the liver is, that we can produce it, at will, in some at least of the lower animals. You know that the "*foie gras*," procured from certain birds, is an article of great luxury among epicures. It is obtained by a very cruel process. Geese, or ducks, are confined in baskets just large enough to contain them, but not large enough to allow them any motion : they are kept continually in the dark also – sometimes even, I am afraid, their eyes are put out, but this I should imagine to be a useless and superfluous piece of cruelty, it being the absence of light, and not the absence of the power of vision, which helps to bring about the desired effect. At the same time the birds are sedulously crammed with food. Under this discipline their livers acquire the requisite size, and greasiness, and the true flavour.

An ingenious theory has been constructed, in reference to the *modus operandi* of this process. The excessive supply of nutriment tends, no doubt, of itself, as it always does, to the production of fat: the constrained state of inaction interferes probably with the right and healthful formation of blood, a matter in which the liver is believed to be a good deal concerned ; then we know, by experience, that the privation of light has the effect of blanching animals as well as vegetables, and thus farther interferes with the due renovation of the blood. In this way the transformation of the liver into a fatty mass has been sometimes attempted to be explained. To what extent the explanation is correct, I will not pretend to say : but it is worth remarking that the fatty liver is very frequently met with in persons who die of consumption ; and in that disease there are various causes in operation tending to modify the constitution of the blood.

The history of these unfortunate fowls is not barren of instruction in respect to the more limited bad effects of full diet, want of exercise, and a short allowance of day-light, upon the "*featherless biped*" man.

The conversion of certain other tissues, and particularly of the cellular, into *mucous* tissue, is by no means a rare thing. It is held that the skin is capable of this transformation—that the skin and mucous membrane are thus naturally convertible into each other. Unquestionably they are at all times closely related, forming a continuous surface even in the sound state, and exhibiting different characters only, perhaps, in virtue of the different conditions in which they are placed, and of the different uses they serve in the animal system. When the cuticle happens to be removed by friction, or by any other means, from a portion of the cutis vera, the exposed surface, as you all know, reddens, becomes preternaturally sensible, is constantly moistened by an albuminous fluid, and approximates very manifestly to the nature of a mucous membrane.

It is the *cellular tissue*, however, that most commonly and most decidedly assumes the properties of a mucous membrane. We find that sinuses, fistulous openings, and tubes in various parts, clothe themselves, at the expense of the cellular tissue, with a surface of mucous membrane. This new tissue is not distinguishable, anatomically, from portions of original mucous tissue. It is true that we do not find it provided with mucous follicles, or with ordinary villi ; but these are no essential parts of true mucous membranes. The membrane by which the surface of a fistulous channel is lined resembles very precisely, in character and qualities, the simpler forms of true mucous membrane ; such, for example, as are seen in the urethra, in the biliary passages, and in excretory ducts generally. Like them it is with difficulty made to take on the adhesive inflammation : and it is for this reason that sinuses of this kind, and chronic abscesses, are so troublesome to the surgeon, and require to be laid open before they can be abolished.

I have already given you instances of the conversion of other tissues into *bone*. At first sight it would appear that nearly all the tissues are susceptible of this change. The brain and spinal marrow, the lungs, the heart, have been found more or less completely encased in bony matter : so that it is common to speak, and to exhibit specimens, of ossification of the pleura, of the pericardium, of the dura mater, and so on. But the truth seems to be that, in these cases,

the ossification has taken place in the cellular tissue immediately subjacent to these membranes ; bony or earthy matter being laid down in that tissue in granular deposits, or in ossific plates. And we may say, with Dr. Carswell, that the osseous transformation is exclusively confined to the cellular, fibrous, fibro-cartilaginous, and cartilaginous tissues.

We have been considering the conversion of natural tissues into other natural tissues. But tissues exactly like the natural are liable to be formed *de novo*, and afterwards to undergo many or most of the transformations that have been mentioned. You may probably have seen, for example, the pleura pulmonalis connected to the pleura costalis by very perfect cellular tissue. Now this new tissue may be converted into other tissues ; into cartilage, or into bone. These are ultimate consequences of inflammation, and as such I shall have occasion to revert to them hereafter. You will in the meantime bear in mind that this is one mode in which very remarkable changes in the bodily structure may be effected.

The intimate texture of parts may be farther altered—not simply by conversion into other known forms of structure—but by an absolute disappearance or confusion of all regular structure. This is usually a consequence, either of the effusion in the natural interstices of the parts, of fluids, which afterwards pass into the solid state, or it is a consequence of the growth of solids which do not belong to the healthy body. In this sketch of general pathology I must content myself with thus briefly alluding to this source of morbid change.

I may as well observe, here, that the alterations, with which we have hitherto been occupied, of the solids of the body, fall, almost all of them, under the head of *lesions of nutrition*, as the French pathologists speak. That is to say, they commence, and have their primitive seat, in that process and place, where the blood, having reached the capillary system of vessels, performs its special purposes. It is in the capillaries that the fluids and solids accomplish their vital union. Each solid receives from the blood, and assimilates with its proper substance, material particles, identical in their nature with those of which it already consists. Each solid gives up also to the blood, and so dismisses, other particles, which before formed a portion of itself, but which have become unfit, or superfluous. Now any departure from this continual building up and pulling down—any excess, or defect, of the particles added, or of the particles subtracted—any irregularity in the manner in which they are deposited — any variation from their right consistence, or in their kind

and quality—in short any deviation from the regular process, as I have briefly described it—is called a *lesion of nutrition*.

The few changes already spoken of, and *not* included among the lesions of nutrition, are : —

The distension of the hollow organs by an undue accumulation of fluids within them ;

The coagulation of the fluids in their proper vessels, excluding however the capillaries ;

The escape of the fluids, as such, cut of and beyond their containing vessels ; and

The solution of tissues, after death, by the chemical agency of the gastric juice.

None of these, properly speaking, constitute lesions of nutrition, although they sometimes lead to them.

Lastly, let us take a glance at the changes of *situation* to which the solid parts of the body are liable. They are sometimes of very serious import.

These changes of place—sometimes the consequence of disease, sometimes its cause, and not unfrequently the cause of death—respect chiefly the viscera — and most especially the viscera of the chest, abdomen, and pelvis. I omit dislocations of joints, as belonging exclusively to surgery.

In the chest, a whole lung may be displaced, and compressed against the vertebral column, by blood, or serum, or air, effused into the cavity of the pleura. An alteration of this kind, whereby one half of the respiratory apparatus is rendered incapable of its special function, cannot be otherwise than full of peril.

The very same causes operating on the left side of the thorax will dislocate the heart, thrust it over to the right of the sternum, where it may be felt, and heard, and seen, to pulsate. This again cannot happen without greatly disturbing the vital function of circulation, and putting life in jeopardy.

Yet neither of these serious displacements are necessarily fatal. Both admit, under certain circumstances, of remedial treatment: as I hope to prove to you hereafter.

In the abdomen and pelvis, the various forms of hernia may be adduced as involving very dangerous changes in the place and relative position of parts. Portions of the intestinal tube are apt to pass through accidental openings in the diaphragm—or between the edges of the linea alba surrounding the navel—or out at the abdominal ring—or through some other natural or accidental aperture. I need not tell you how fearfully life is compromised when, in consequence of such faulty position, the bowel becomes constricted—when its contents can no longer pass onwards, and inflammation, or gangrene, are present or

impending. Even when there is no strangulation, the mere displacements to which the escape of the contents of the abdomen and pelvis from their natural limits gives rise, may be productive of much discomfort, deformity, and danger. Of this the historian Gibbon presented a remarkable example. He had an immense scrotal hernia; so large it was, that it hung down very nearly as low as his knees. After his death it was found that almost the whole of the omentum, and the greater part of the colon, had descended into the scrotum, and had dragged the stomach after them; so that its pyloric orifice lay close to the abdominal ring.

Akin to hernia is that partial displacement of the bowel in which a portion of it passes, not through any natural or accidental opening, but into the bowel itself: just as one portion of the finger of a glove is sometimes pulled into the remaining part, by the withdrawal of one's hand. The contain*ed* portion of intestine is liable to be nipped and strangulated by the contain*ing* portion—and all the peril of hernia results, with much less chance of relief by art. This state of things is called *intus-susception*.

Exactly of the same nature, though less alarming, is *prolapsus* of the rectum, or of the vagina. Here also a portion of the tube passes into the contiguous portion; but being near the extremity of the canal, the inverted part protrudes externally, and becomes, in most cases, a source of distress and suffering, rather than of danger. Inversion of the uterus is another example.

Thus much, then, of the changes to which the *solid* parts of the body are subject, in *bulk*, in *form*, in *consistence*, in *texture*, in *situation*.

You cannot fail to perceive the injurious effects which many of these changes in the various solids, are calculated to produce upon the movements and working of the living machine: how some of them must impede or derange its natural action; some stop that action altogether.

Now the fluid parts of the body are liable also to alterations, which, if they are not always so obvious as those of the solids, are certainly not of less moment.

You are probably aware that, for many centuries, the fluids were supposed to be the primary agents in every form of disease: that all maladies were attributed to some acrimony or peccant state of the humours; and that however else the theories of medicine might vary and fluctuate, the *humoral* pathology, till a comparatively recent period, ran through almost all of them. At length, the absurdity of the hypotheses, and still more the dangerous practice which this doctrine involved, began to be manifest, and led to its total abandonment. Rather more than a century and half ago, the foundation of the opposite doctrine appears to have been laid, by the writings of Glisson in this country, and by those of Baglivi in Italy; and presently the notion came to prevail throughout the schools, that all the morbid conditions of the body had their exclusive origin in the solids. The pendulum of opinion swung at once, as is usual, into the opposite extreme of error. It promises, in our time, to settle at the proper medium. The humoral doctrine still indeed finds favour among the ignorant, and is commonly adopted by the quack: a circumstance which illustrates the fact that the mischievous influence of unsound theories survives the duration of the theories themselves. The scientific physician of the present day can only wonder how exclusive solidism, or exclusive humoralism, should ever have found advocates.

EXPERIMENTS
ON THE
MOTIONS AND SOUNDS OF THE HEART.

BY THE LONDON COMMITTEES OF THE BRITISH ASSOCIATION FOR 1838-39, AND 1839-40.

[*For the Medical Gazette.*]

</div>

THE following report consists of two distinct portions, the former describing the experiments performed at King's College, in 1839, by the London Committee for 1838 and 1839, and the latter detailing those of the Committee for 1839-40, performed at the Marylebone Infirmary in the present year. The former series, performed in conjunction by Professor Todd, Dr. C. J. B. Williams, and the Reporter, with occasional assistance from Dr. Roget, were successfully commenced but were not completed, owing to the difficulty of procuring subjects, and other circumstances beyond the control of the Committee. No report of those experiments was, consequently, presented at the Birmingham meeting, or has yet been published; and an account is, therefore, now prefixed to the report of the proceedings of the Committee for the current year.

The experiments of 1838-9 were performed with the view to determine the physical and pathological causes of certain modifications of the motions and sounds that are presented by diseases—a chief object being to ascertain how, by mechanical and other irritations, and by displacements of the heart, murmurs could be produced; how also by inflammation. Whether, for example, the pericarditic friction sounds depend on deficient lubrication of the pericardium, or vascular

turgescence, or are dependent solely on the effusion of lymph ;—how far, also, the natural sounds might be impaired by interrupting the action of the valves in the living subject, or by spontaneous or artificially excited abnormal action in the muscular parts of the cavities without structural lesion. Another inquiry was this—how far do the motions and sounds of the heart in the lower animals correspond with those of the human subject : whether, for example, in birds and other animals that differ more or less from man in their cardiac anatomy, there be not corresponding differences in the cardiac sounds and motions. To those questions the experiments for 1838-9 supply answers, in most cases, which are satisfactory, in the opinion of the Committee, to as great an extent as could be calculated on from so limited a number of observations : they feel, however, that the experiments were too few to decide any point of much difficulty or importance, and that further trials, under more favourable circumstances, are very desirable.

The experiments referred to are the following :—

EXPERIMENTS FOR 1838-9.

OBS. I.—14th June. Present—Doctors Roget, Todd, Williams, and Clendinning.

Subject—An ass about three months old. Pulse about 60 ; regular. At 8 o'clock, A.M., a long fine needle, with a silver canula, was passed into the chest at the left margin of the sternum between the ribs to the depth of two inches. The needle immediately exhibited motions corresponding to those of the heart. The needle was withdrawn, and aqua ammoniæ, diluted with four or five parts of water, was injected through the canula. The pulsation of the heart became immediately weak and very irregular, with intermissions.

10 o'clock. — Heart's action natural ; pulse 77.

12 o'clock. — Pulse 70. Occasionally irregularly accelerated for a few beats.

2 P.M.—Still no abnormal sound.

5 P.M.—Pulse 78.

15th June.—7 A.M. Pulse about 80. At half-past 7, half an ounce more of solution of ammonia was injected as before ; after which pulsations weak and irregular at first, but afterwards regular. Pulse 96 ; strong, with clear sounds.

12 o'clock.—Pulse 72. Sounds natural and regular. First sound somewhat prolonged, with suspicion of murmur.

16th.—Sounds strong. Pulse 56. Canula again introduced at the root of the xiphoid cartilage into the pericardium. Some blood followed the needle ; then some strong solution of salt was injected, whence irregular accelerated action of the heart.

4 P.M. — No murmur present. Both sounds distinct. Intermission every fourth or fifth beat. (C.)

5 P.M.—Pulse irregular. First sound double. Generally in triplets, followed by intermission, the second sound being absent in the weak strokes preceding the intermission, but distinct and loud at other times. Pulse 56, but variable. (W.)

17th.—3 P.M. Pulse 56. Still occasionally retarded. Both sounds now rough. Roughness most apparent about the base of the left side, and scarcely audible in the carotids. (W. and T.)

18th.—7 A.M. Dead. But yet warm. Much blood escaped from subclavian vein on opening chest, and coagulated afterwards. A mass of greenish-yellow lymph in the mediastinum. The cellular membrane highly vascular, and easily torn. Flakes of lymph on lower anterior left lung. External pericardium marked with many straight vessels, and intermediate red striæ, giving bright redness to the whole. Same, in a slight degree, the interior pericardium, which contained two ounces of yellow serum. At base of heart most redness. Cellular substance there somewhat infiltrated with serum. Whole interior of surface of heart healthy, except from slight thickening and opacity of mitral. A wound, plugged with lymph, found in anterior face of right ventricle.

OBS. II.—17th. *Subject*—An ass ten weeks old. Pulse 48. Regular and pretty strong. Animal weak. By pressing between the fingers and thumb the cardiac region, the thumb being on the third rib and left side, a loud blowing was excited with the first sound, which ceased on removing the pressure. After several repetitions of this experiment, a short filing sound heard (by two members of the committee), after the second sound, the first being clear. On repeating the pressure more strongly, two murmurs were heard (by the same observers), one with the first sound, and continuing after it, and one with the second sound (which was also weakened), and continuing after it.

After being fifteen minutes at liberty, the animal had a deep-toned blowing with first sound, which soon ceased, but the murmur after the second sound continued.

20th.—8 A.M. Same murmur or filing after the second sound as before. A long needle was passed two and a half inches deep vertically to the fourth rib, along the upper margin three inches from the sternum. A strong double motion was given to the needle, and a blowing, resembling a cooing, accompanied the first sound. The heart's action was increased, though the animal seemed faint.

21st.—Pulse 60. The needle again in-

troduced three inches : as before the needle presented rhythmical movements, sternad and dorsad. That dorsad being slow and forcible, and synchronous with the first sound. That sternad being sudden, like a fall back from gravitation, and accompanying the second sound. A murmur of a blowing or whistling kind heard with the systole and diastole also, the latter variously described by different observers. Murmurs and sounds were variously altered and impaired by pressing the needle flat in different directions. On withdrawing the needle, murmurs were heard with systole and diastole, described as rasping and filing respectively. (W. and T.)

Natural sounds distinct. The needle was introduced a second and third time. After the third withdrawal of the needle a loud creaking was heard with both sounds by two observers, but no constant abnormal sound by the third. The creaking was reported (W. and T.) to continue some minutes, when the natural sounds returned, with only slight mumur with the second sound.

22d.—Animal dead (7 A.M.) and cold. Considerable effusion of bloody serum in right pleura and mediastinum. Some ecchymoses and marks of perforation on left ventricle, with corresponding marks and changes on the pericardium. Perforation three-quarters of an inch below and behind, or nearer to the apex than the semilunar valves. The needle had transfixed the left ventricle, slightly wounding the mitral, and penetrating the posterior wall. The anterior lamina of the mitral had ecchymoses, and the posterior lamina was perforated near the edge, with a small fibrinous excrescence on valve. The wound passed through the opposite posterior wall of left ventricle, around which there was ecchymosis under the pericardium. The aortics were healthy.

Obs. III.—23d. *Subject*—An ass of ten weeks old. Half-past 7 A.M. Pulse 60. Strong and distinct. A canula was introduced about an inch from the xiphoid cartilage, and for about an inch in depth, when a sound, first as of rubbing, afterwards as of blowing, accompanied the latter part of the systole. About an ounce of brine was then injected, when the pulsations became tumultuous and irregular, and the sounds obscure, with loud gurgling, (probably from injection of air).

3 P.M.—Sounds obscure, but more distinct towards the base, when a short creaking (W. and T.) or blowing (C.) accompanied the first sound, which was not audible in the arteries. Pulse irregular.

24th.—3 P.M. Pulse 90, and regular. Sounds more distinct than yesterday, and towards the base of the heart, accompanied by leather or parchment sound. Respiration

laborious. Tender near the heart, but eats well, and is lively.

23d.—7 A.M. A loud parchment rubbing murmur with each of the sounds, which otherwise were distinct and natural. Pulse 80.

8 A.M.—Jugular vein opened. Copious hæmorrhage. Heart's action became rapid, with slight rubbing sound. Soon, however, became slow and strong, with superficial loud grating or rough sound, and, becoming gradually weaker, soon ceased.

One ounce of serum in left pleura. Two to three ounces in pericardium. External pericardium exhibited several striated patches of minute vessels. The cellular tissue was infiltrated with serum, and the serous membrane was easily detached. No lymph on the inner or free surface of the pericardium, but the heart was completely coated with thin, membraniform, soft lymph; thickest at the septum, and near the base. On the anterior and posterior surfaces numerous minute depressions or lacunæ were seen in the lymph. The lymph was easily removed. On the left ventricle near the apex was an oval space of an inch by an inch and a half of bright red patches, seeming partly vascular, partly ecchymotic, about the middle of which was a punctured wound, and a clot in the muscular tissue beneath, and some ecchymoses under the corresponding endocardium. The interior of the heart healthy. The serum from the pericardium after standing separated into crassamentum and liquid.

Obs. IV.—23d. *Subject*—A stout ass two months old. Pulse 60-70. Strong, with sounds very loud.

A quarter to 4 P.M. A needle was introduced at the upper edge of the fourth rib, three inches from the sternum, and one inch deep. The heart's action was accelerated, with obscure blowing with the systole. The needle being withdrawn, the heart's action was slower, with double creaking or leather sound reported by two observers as accompanying both sounds, which became stronger after a few minutes. Heart's action varying in regularity.

A quarter of an hour after. Leather sound at the site of the puncture ; not at all at the apex. Natural sounds there quite distinct.

25th.—7 A.M. Both cardiac sounds loud, with sounds of friction at the basis cordis.

26th.—7 A.M. Normal sounds and friction sounds as before. A long needle three times introduced in different directions between the third and fourth ribs, and three to four inches from the sternum, without any marked effect, except sometimes, on strongly depressing the handle towards the sternum, a blowing with first sound was

heard, the second sounds being normal. (Rubbing rather than blowing sound. C.)

On first introducing the needle, a scratching noise was sometimes heard, with the systole, as if from the point hitching against the heart's surface.

A fine curved tenaculum, about two inches in the curve, was then passed two to three inches from the sternum, behind the third rib, with the point towards the spine, and, when at the greatest depth, the handle was depressed towards the sternum, so as to move the hook outwards towards the ribs. A loud blowing then attended the first sound, which was still distinct. The second sound was wanting when the handle was most depressed, and obscure when the handle was somewhat raised, and restored to full force when the hook was withdrawn.

Half an hour after, the first sound was accompanied with blowing between the first and third ribs, while a friction sound accompanied the second sound. (The Reporter called it altogether friction sound, with both systole and diastole, but varying in hoarseness or roughness.) It was faintly audible in the carotids.

Half-past 3 P.M. Still slight friction and blowing (roughness only of frictions. Reporter.) increased after the animal struggled. The tenaculum was again introduced, and manipulated as before, and again the second sound was stopped by drawing at the root of the arteries, and restored on relaxing the hold, the first sound being accompanied by a loud whizzing, and the hoarse or rubbing sound being indistinct, if not absent.

On withdrawing the hook a transitory crackling was heard. On the introduction of the hook, the heart's action became tumultuous and irregular, and, on withdrawing it, very rapid. Pulse 112. Half an hour after, the pulse still 112, and the first sound accompanied by murmur.

27th.—A quarter past 7, A.M. Sounds as before. Rough murmur, as of friction, with first sound especially. The animal then pithed, and artificial breathing established, and chest opened. Heart was acting vigorously, with the sounds distinct and normal.

FIRST EXPERIMENT.

On introducing a finger into the right auri-ventricular orifice, first sound was accompanied with a whiz, and wanted its flapping beginning. The whiz was accompanied by a thrill sensible to the finger introduced. The whiz ceased, and the systolic flap returned on removing the finger. This experiment was repeated several times with the like results.

SECOND EXPERIMENT.

The hook was introduced through the auricle to hook up the tendons of the mitral valves, when the flapping was impaired, not suppressed, and the whiz was uncertain.

THIRD EXPERIMENT.

A finger placed on auriventricular opening externally experienced the same vibratory or jerking motion as would be felt over the aortics ; and to the eye the same motion was visible in the former during the first sound at its commencement, as at the arterial openings during the second sound. (C.)

FOURTH EXPERIMENT.

A blunt bistoury was introduced into the auri-ventricular opening through the auricle, and the tendons of the septal lamina of the mitral were cut partially, when the flapping of the first sound was impaired, but not destroyed.

On examining the heart were found several marks of perforation of the large arteries, anteriorly to the valves ; the perforations were just at the opening of coronary, but no valve was wounded. There were ecchymoses at the external mouths of the perforations, and attached to one wound was a clot with a fibrinous peduncle. On the surface of the right ventricle, corresponding to the infundibulum, the surface was injected, and roughened by lymph, with several scratches and punctures. The lymph was small in quantity and granular in appearance. A wound in the septum was plugged with lymph, as were all the flesh wounds in the interior of the heart.

OBS. V. — 29th. *Subject* — A donkey three months old. Half-past seven A.M. Heart's action quite normal. A tenaculum passed four inches from the sternum, between the third and fourth ribs : the handle having been lowered towards the spine, there was a whizzing heard with the first sound ; but the second sound was only a little weakened. The whizz or blowing continued after the experiment, with the systole, and after the flap of the valves, but soon became intermittent, and gradually disappeared.

30th.—A fine canula was passed through the sternum an inch from the xiphoid cartilage, and about twelve ounces of warm water were injected. The cardiac sounds became presently apparently distant, especially towards the sternum. On withdrawing the tube, the sounds were still distant, with little impulse, but were otherwise normal, except that occasionally the systole was accompanied by blowing during embarrassed respiration. A tumor formed under the integuments of the sternum, through which the cardiac sounds were very faintly heard, and without impulse. Heart's action much accelerated.

July 4th.—Animal pithed, and artificial breathing established. The experiments on the mitral valves then repeated. The left auricle was inverted by the finger, and the valves impeded or kept asunder by the finger in the auri-ventrical opening, when various murmurs accompanied or followed the first sound; the second sound being simply either much weakened or suppressed, and the normal sounds returned on the withdrawal of the finger. This experiment was often repeated with similar results.

A finger being placed on the exterior circumference of the mitral and aortic valves respectively at the same moment, similar jerking motions perceived in each at the closure of the valves and evolution of the two cardiac sounds. The finger when in the auri-ventricular opening was sensible of something like flapping, pushing, and stretching as it were, in and by the valves; and the supposed edge of the valve was felt tense in systole, and if divided by the point of the finger the edges of the opposite valves were thought to give a feeling of resistance, such as valvular tension must cause, supposing such tension to occur. The first sound was protracted and dull, wanting the sharply defined beginning, such as a flap would give, when the valvular action was interrupted by the finger.

The first sound was obscure, but audible on extraction of the heart, when the organ was irritated and contractive.

OBS. VI.—July 3d. *Subject*—A turtle, weight 150 lbs. No distinct pulsation could be heard externally. After decapitation and removal of the callipée, the heart was felt by one of the committee pulsating regularly, and two distinct sounds were heard (W.) with an interval between; the heart ceased beating too soon to allow of the other member of the committee (C.) making any satisfactory observation.

OBS. VII. — *Comparative observation.* The observations of the committee on the motions and sounds of the heart had been previously made almost exclusively on donkeys and dogs—animals whose cardiac structure and modes of action are generally known to agree very nearly with those of the human subject. It was therefore thought very desirable to extend their investigations more widely over the scale, as by such means, it was thought, some useful generalization might be obtained, and the views of the committee be at the same time subjected to a new and interesting test, and if sound fully confirmed, but if defective, corrected; and in any event that their future conclusions would be based on a greater variety of facts, and a more comprehensive induction. The committee, therefore, made arrangements for the purpose of visiting the Zoological Gardens, and examining as many of the animals as could easily be approached by strangers, for the purposes of auscultation, &c. Before visiting the gardens the committee met at the Hunterian Museum, for the purpose of inspecting the preparations illustrative of the physiology of the heart that exist in that national collection, and were obligingly assisted in their search by Mr. Owen, the distinguished professor to the Royal College of Surgeons. With the aid of the anatomical data collected at the Royal College of Surgeons, the committee then entered at once on their examination of the living animals. Before stating any particulars of our observations, it is proper to say that in our examination of the wilder animals we were much indebted to Mr. Youatt, the distinguished veterinary surgeon of the establishment, without whose kind assistance it would have been out of our power even to have attempted any thing in several instances. Even with Mr. Youatt's aid we found it extremely difficult in many cases to make satisfactory observations, so that in but a portion of the subjects was it found practicable for the whole of the committee to verify results to their satisfaction.

The animals sufficiently examined by all are distinguished in the following enumeration:—

1. The ostrich.
2. The ourang-otang.
3. The leopard.
4. The seal.
5. The Balearic crane.
6. The Brahmin bull.
7. The common crane.
8. The puma.
9. The Indian antelope.

Other animals examined to the satisfaction of some members of the committee were

10. The elephant.
11. The dromedary.
12. The antelope.
13. The water buffalo.
14. The giraffe.
15. The lion.
16. The nylghau.
17. The Wapiti deer.
18. The hyæna.

In No. 1. (the ostrich) the pulse at the heart was very vigorous, and about 60 in the minute. The systolic or first sound was long and obtuse, and the second or diastolic sound was short and rather obtuse.

In No. 2. (the ourang-otang) the pulse was quick, and the cardiac sounds and rhythm like those of the heart of a child very exactly.

In No. 3. (the leopard) the pulse was 60, the first sound normal, but the second rather

indistinct as compared with the human standard.

In No. 4. (the seal) pulse not materially different from the human. First sound long and obtuse, second sound short and clear.

In No. 5. (the Balearic crane) pulse 130 to 140. Animal phthisical. First sound long and obtuse, second sound indistinct.

In No. 6. (the common crane) first sound short, and no second sound heard.

In No. 7. (the Brahmin bull) pulse 80. Animal phthisical. First sound long and obtuse, second sound indistinct.

In No. 8. (the puma) pulse 86. Animal sickly, probably phthisical. Grating murmur with the first sound.

In No. 9. (the Indian antelope) long obtuse first sound ; short flapping second sound.

In No. 10. (the elephant) pulse 36 ; long and obtuse first sound, and relatively short and flapping second sound.

In No. 11. (the dromedary) pulse 48 ; long and obtuse first sound, short second sound.

In No. 12. (the antelope) the first sound longer and duller, the second sound shorter and sharper.

In No. 13. (the water buffalo) pulse 60. Blowing and murmur after the first sound ; no second sound heard.

In No. 14. (the giraffe) pulse 50. Second sound sometimes double.

In No. 15. (the lion) first sound long and obtuse, second sound short and flapping.

In No. 16. (the nylghau) first sound normal, second sound indistinct.

In No. 17. (the Wapiti deer) pulse 60 ; first sound long and obtuse, second sound short and flapping.

In No. 18. (the hyæna) long obtuse first sound, short second sound.

Some other animals were attempted, but without success, viz. the dzagetai or wild ass, the rhinoceros, the cassowary, and some others. As a general observation the committee may state, that wherever the second sound of the heart could be distinguished, the character of both sounds, and the rhythm of the heart's motions, appeared to correspond with those of the human heart ; due allowance being made for differences of size in the animals, differences of temperament, and the circumstances of excitement or of disease under which many of the animals laboured when they were subjected to auscultation, &c.*

---

* The conclusions from the preceding experiments will be subjoined with those of the experiments that follow in the report for the current year.

AN INQUIRY INTO SOME OF THE CONSEQUENCES AND CAUSES OF FAILURE

OF THE

NEW OPERATION FOR THE CURE OF STRABISMUS OR SQUINTING.

By. E. W. Duffin, Esq.
Surgeon.

[*For the Medical Gazette.*]

In my communication of last week it was stated that, when the adductor muscle was divided, among other reasons for the eye not turning outwards might be assigned the counteracting agency of the oblique muscles, both of which tend to retain the globe in the centre of the orbit. Indeed, in some cases in which the strabismus is very considerable, and of long standing, these muscles become implicated in its production : hence we occasionally find, as already stated, even after the thorough liberation of both eyes internally, in as far as the distortion may proceed from a morbid shortening of the adductor muscle, or other adventitious cause, that the pupils are still capable of being turned somewhat inwards, and many days, or even weeks may elapse, before they attain the fullest extent of divergence from their former situation. When the eye-ball has been so firmly detained in its abnormal position by any morbid change of structure in the cellular tissue as to wholly prevent it from being turned outwards, or to admit of it being so turned only in a very limited degree, then the tardy return of the pupil to its proper position may, in some measure, depend on the external rectus having been so long over-extended as to have lost a portion of its contractile power.

The superior oblique muscle rotates the eye in a direction downwards and inwards ; and the inferior oblique being its antagonist, rolls it in the contrary direction ; but neither of these muscles, either singly or conjointly, has any disposition to approximate the pupil to the inner canthus, beyond the visual centre of the orbit, unless it has been previously involved in the production of strabismus. If such, then, be a part of the functions of the oblique muscles, it must be evident that when they both act together, they will have the effect of steadying the eye in

the visual centre of the orbit; or, in other words, we are indebted to the conjoint action of these muscles for the power of fixing the globe of the eye when we look steadfastly at an object placed immediately before us, and at that distance from the eye at which we see it most distinctly ; this being the position of the organ in which the exertion of such a steadying power is of the most importance. If, moreover, the focus of the eye be ever changed, so as to accommodate it to the various distances at which we survey objects, these muscles must be very powerful agents in accomplishing this object, by compressing the central portion of the sphere slightly between them, and against the cushion of fat which lines the nasal surface of the orbit ; thus not only increasing the distance between the cornea and that portion of the retina on which the image is depicted, but also rendering the cornea itself more convex. This presumed use of the muscles, however, I throw out as a mere conjecture, being aware that physiologists in general maintain a different opinion. The importance of steadying the eye, under particular circumstances, against any inadvertent contraction of the recti, and of accommodating its focus to the required distance, is too obvious to need comment ; and I think, on reflection, we shall be inclined to admit that the same end could not be so efficiently attained by any combination of agency on the part of the recti muscles. If this view of the functions of the two obliques be correct, we may conclude that when the adductors are incapacitated by the division of their tendons, it is mainly by the co-operation of these agents, aided by the sympathetic influence that exists between the two organs, that the eye-ball is steadied, and the pupil retained in the visual centre of the orbit ; although it may occasionally happen, from certain adventitious causes, that the obliques are incompetent to resist the contraction of the external recti muscles.

Such was the view that I entertained of the functions of the two oblique muscles ; but it occurred to me that, instead of resting satisfied with an empty theory, or dissecting and pulling the dead muscles in the direction of their fibres, in order to observe what effect their contractions produce on the eye-ball, it would much more satisfactorily decide the question, could we in any manner witness their own uncontrolled influence on the living eye. In order, then, to have an opportunity of observing this, I procured a middle-sized dog, and, aided by my friend, Mr. Samwell, of the Marylebone Dispensary, instituted the following experiments :—

I first divided the adductor of the right eye. The effects were such as ordinarily follow the division of this muscle, and need not be further insisted on. I next cut across the second belly of the superior oblique, and instantly the globe performed a rapid and most distinct semi-revolution upwards and outwards, in the direction of a line running diagonally from the origin of the inferior oblique muscle through the centre of the lacrymal gland. This movement was forcible, quick, and decided ; the pupil as speedily returning again to near its proper site. By irritating the eye with the handle of the scalpel, we had an opportunity of witnessing this movement a great number of times, so as to satisfy ourselves respecting it in every particular. Besides rolling the eye-ball in the manner just described, this action of the inferior oblique caused the globe also to *protrude* in a most remarkable degree, fully a third part of the sphere being thrust, on each successive contraction, beyond the boundary of the orbit, so that the under surface of the ball was presented to view, but as quickly disappeared again when the eye recovered its position, which it did only in a limited degree, by the action of the inferior rectus. This advance of the eye-ball, and its revolution in the diagonal line already indicated, is precisely what might be inferred from the course of the fibres of the inferior oblique muscle, and from their winding round so large a portion of the sphere. The extreme expansion of the tendon is far beyond the greatest diameter of the ball, reaching, in fact, when carefully dissected, to near the entrance to the optic nerve.

I next divided the inferior oblique, and the globe was no longer advanced on the eye being irritated ; but the pupil was pulled to near the outer canthus by the action of the external and superior recti muscles ; and had it not been for the restraining power exerted by the inferior rectus, would have wholly disappeared.

My next experiment was to divide the inferior oblique alone in the opposite eye. As soon as this was accomplished, which I did by passing a curved bistoury beyond it, with the point pressing against the floor of the orbit, and then pulling it sharply out, the eyeball was first instantly rotated in the direction of the fibres of the second belly of the trochlear muscle, and then drawn obliquely upwards towards the pully through which it passes. This second effect cannot, of course, ever manifest itself unless the inferior oblique be previously divided, as it arose in consequence of the eye being freed from the restraint of the latter muscle. The globe of the eye was considerably advanced, as in the former experiment, the lower surface of the eyeball being brought into view. This advance of the globe was in some measure owing to its being held bound by all the other muscles, and consequently unable to follow the full rotatory movement that would have been imparted to it had their several insertions been cut. But, of course, had I divided these, the eye-ball would have been so detached that it would have been impossible for us to have formed so correct a judgment as we were enabled to do, by making allowance for the opposition which the superior oblique met with from their conjoint actions. The true antagonist of the trochlear muscle, it is quite clear from the foregoing narration, is the inferior oblique; and it was only necessary to divide this latter muscle to allow the former to show in what direction it would pull the eyeball in the event of the operation of dividing the *inferior* oblique being undertaken, as proposed by Dr. Franz, had his attempt on the superior oblique failed (*vide* Lancet, June 24, 1840.) Had the Doctor, indeed, divided the superior oblique muscle, as he states he did, what would have been the unfortunate position of the patient's eye? Why, the pupil would have rolled upwards and outwards, and been lost to view under the lacrymal gland. Besides, it must be remembered that most animals are furnished with an additional muscle—the *suspensorius*, for the purpose of retaining the eye-ball *in situ*, and obviating the inconvenience that might otherwise be experienced from the dependent position of the head, especially during feeding. This muscle, which in ruminants is funnel-shaped, and in the carnivora quadripartite, is very powerful, and embraces the whole posterior half of the sphere. It arises circularly from the margin of the foramen opticum, encloses the optic nerve, and is inserted as just stated. Now if the eye was thrust out in the manner described, notwithstanding the additional resistance which this muscle would oppose to the protruding action of either of the obliques, on its antagonist being cut across, what would have been the consequence had the same operation been performed on the human eye, surrounding the posterior surface of which no such muscle is to be found?! I am very earnest in pointing out these facts, in order to prevent any one thoughtlessly dividing either of these two muscles; though I am informed another surgeon asserts that he has cut the *inferior* oblique. I seriously trust that he is mistaken, and that for once his usual dexterity has, in this respect, failed him. If either of these gentlemen be still of opinion that he divided the muscles in question, let him repeat the above experiments on an animal, and I think he will coincide with me, and congratulate himself that he did not succeed in his intentions.

Another effect of the division of either of these muscles we observed to be an incredible enlargement of the pupil; to such an extent, indeed, that the iris formed merely a narrow band, encircling the inner margin of the cornea. A trifling enlargement of the pupil is a common effect of dividing the adductor: hence it would seem that a certain degree of compression is constantly being exerted on the eyeball by the action of the various orbital muscles; and that the contractions of the iris, as has long been ascertained, do not depend entirely on the degree of light to which the eye is exposed, but are in a great measure attributable to the quantum of pressure to which the sphere itself is subjected.

I may here mention, that it is my intention not only to repeat the above experiments, but to institute a series of others of a similar nature on all the muscles of the eye, with a view to ascertain their positive functions singly and collectively, if this information can be acquired by such means. The re-

sults of this inquiry shall be made known to the profession hereafter.

The portion of the retina which corresponds with the axis of the eye is usually regarded as being more sensible than the rest of the membranous expansion of the optic nerve. No doubt there is general sensibility over the whole of the retina, by which we perceive the outline of a great number of objects; but if we fix the eye upon any one object, or upon any particular part of an object, the image of each separate portion successively must be traced upon that part of the retina in the axis of the eye. Now, whether the superior sensibility and aptitude to convey impressions to the brain be inherent in this portion of the retina, *i. e.* an original property of the part, or only the result of habit and constant employment, has been a matter of conjecture*. This question, however, now appear to be capable of a decided reply. The property is inherent in the particular part alluded to. When a patient presents himself who squints very much, we almost invariably find that his vision is obscure, and indeed, as has been already stated, in some cases almost amaurotic. One obvious reason of this imperfection of vision is the image not being depicted on the most sensitive portion of the retina; since immediately on the eye-ball being liberated, and its axis being made to correspond with this portion of the retina, vision is improved and becomes much clearer as soon as the eye recovers the first shock, and the temporary state of congestion induced during the performance of the operation, by the forcible efforts of the patient to close the eyelids. Were this portion of the retina not primitively endowed with superior visual sensibility, it would require some little time to educate it to the performance of its new function; but, on the contrary, it evinces in some degree its peculiar capacity from the first moment that it has the power of doing so, though it afterwards for several days improves by practice.

Strabismus Divergens (External Squint or Leer.)

This affection is of much less frequent occurrence than the ordinary squint,

* Walker's Philosophy of the Eye, p. 190.

strabismus convergens. Out of upwards of 400 cases that I have examined, I have only met with fifteen examples; and of the operations performed upon these, not one has been, strictly speaking, successful, although they have all been improved in a trifling degree. The external cast, strabismus divergens, has been supposed to proceed from a similar cause, and to be analogous in nature to the more common squint, strabismus convergens; but in many respects it differs from it materially both as regards its pathology and, as just stated, in the degree of success that attends the operation.

The intimate pathology of the affection still remains a mystery: there are certain facts, however, deserving of notice, that throw some light upon it, and at once point out that a remarkable difference exists between the two diseases in relation to their proximate cause. These I shall state, and leave it to physiologists hereafter to explain them.

A person affected with ordinary internal strabismus, provided the eye be not tethered by adventitious adhesions, or a thickened and contracted state of the submuscular structures, can turn the eyes in any direction he chooses, by an effort of the will; while a person affected with external strabismus is generally limited in this respect. He can direct either eye outwards in looking at an object placed at the side of him, while the opposite eye *turns inwards to the full natural extent; but he is incapable of directing both eyes inwards simultaneously.* Now this is a very singular fact. Why, if he possess the power of the *adductors* separately, so as to make the axes of the two eyes, when turned to either side, correspond in the fullest extent, should he not be able to call these adductors into simultaneous contraction, and make the two pupils converge? He has power, when he makes this effort, only over the undistorted eye: the pupil of the other does not pass the centre of the orbit. It is evident that both adductors are capable of the fullest degree of contraction when they act in concert with the abductors of the opposite eyes respectively; why then should they be unable to act together? This is a curious circumstance, and only to be explained by admitting that the two adductors

have lost that sympathetic * power which enabled them to contract together; and the loss of which power, it may be presumed, allows the external rectus of the faulty side to turn the globe outwards, and produce the distortion. But a circumstance that renders this phenomenon still more remarkable is, that such is precisely the power that persons possess over their eyes who have had one or both operated upon, a sufficient time having elapsed to admit of a reunion of the divided tendon to the sclerotica: they can then turn either eye completely to the nasal canthus, while its fellow is directed outwards, but they cannot turn both inwards together.

When a person who has had the muscle of only one side divided attempts to cause the eyes to converge, his power is limited to the intact organ. If the adductor tendons of both have been separated, then neither pupil can be drawn beyond the centre of the orbit in a *horizontal* line, unless vision be directed to an object placed at one side, and the internal rectus of the one eye act in concert with the external muscle of the other; but both can be made to incline *slightly* inwards and downwards; this, however, arises from the contraction of the inner fibres of the inferior rectus, and not from that of the adductor muscle. A person affected with true paralysis of the adductors, as I have just ascertained by examination of a patient so afflicted, and already alluded to, has no power over that of either side, whether the effort to exert the muscles be made conjointly, or in conjunction with the abductor with which each respectively co-operates in performing the simultaneous lateral movements of the eye.

The fact that *complete* paralysis can occur in one or both of the adductors, to the exclusion of the other muscles of the eye, tends to throw considerable light on the pathology of strabismus divergens. Out of the cases I have examined, three have been decidedly of this description, being complicated more or less with other symptoms of cerebral disease, and paralytic loss of muscular

power either local or general. Hence I am disposed to conclude that the more common proximate cause of external strabismus is a partially paralytic condition, at all events, of the consentaneous functions of the adductor muscles, by which the natural power of the abductor becomes comparatively excessive, and sufficient to draw the eye outwards. Another circumstance that leads me to regard loss of power of some description in the adductor as the immediate cause of this affection, is, that we so frequently find the distorted eye large in comparison of its fellow—a condition that we know now is a common result of enfeebling the retaining powers.

When the external rectus is cut across, we do not find the eye instantly to start into its proper position as it does when the internal muscle is incapacitated. The pupil goes more gradually to the centre of the orbit, as if it were not drawn there by an active force, but went there because the restraining power no longer opposed the movement. After the operation, moreover, the capability of moving the eyes towards the nasal canthus by an effort of the will remains precisely the same as before: nothing has been gained in this respect: the patient has not acquired the power of directing both eyes inwards simultaneously. In fact, all the apparent advantage obtained is, that, when quiescent, the pupils of both eyes occupy the visual centre of their respective orbits, instead of only one doing so, while the other is directed outwards. The appearance of the patient in this respect may be somewhat improved, but to counterbalance this, the eye, in consequence of its retaining powers being still further weakened, is liable to protrude, and look more ungainly than before. It is, therefore, a matter for consideration to be determined by further practical experience, whether the division of the external rectus is a measure to be generally advised or not, as likely to improve either the sight or the expression of the individual. Of the precise nature of the loss of power in the internal muscle I confess I am unable to offer any satisfactory exposition; at least none that will explain how this muscle retains its contractility to the fullest extent so long as it acts in harmony with the abductor of

* I denominate it *sympathetic*, because it is clear if the adductors can under any circumstances turn the eyes thoroughly to the nasal canthus, they have not lost their *absolute* power of contraction.

the opposite eye, and ceases to possess this power, when called upon to act in conjunction with its fellow. The third and the sixth nerve, it would seem, can act together, but not the two third nerves. The sympathy that ought to subsist between them is in abeyance, and it appears to me that unless we can restore this, we are not very likely to gain much advantage by the operation.

Finally, let us suppose a case of strabismus divergens proceeding from a contracted condition of the external rectus muscle, while the adductors and obliques retained their healthy condition. What would be the likely results under such circumstances of dividing the abductor muscle ? It appears to me that we should in all probability produce a most incurable strabismus convergens, because we should have three muscles left at liberty to contract to any extent of which they might be capable, but more especially the adductor ; whereas the case is very different when the internal rectus is divided, the abductor being still opposed by the two obliques.

THE VARIOUS OPERATIONS FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

THAT many different opinions should be entertained as to the best method of performing the operation for strabismus is what might very naturally be expected ; and it is also very natural that each operator should have a peculiar affection for any little invention of his own. I should have remained, as hitherto, a silent spectator of the various claims to superiority in the performance of this simple, beautiful, and truly scientific operation, had the different competitors for public favour been content with the recommendation of their own plans without decrying those of others, often most unreasonably as well as unjustly. Having no invention of my own to bring forward, having seen the operation for strabismus performed in nearly a hundred cases, and having operated myself several times, I have anxiously endea-

voured to form an impartial judgment of the merits of the different methods of its performance. As the operation for strabismus is at present rather a novel one, I trust that the results of my experience upon the subject may not prove entirely useless or uninteresting to those gentlemen who may not have had quite so wide a field for observation as myself.

There are two things especially to be desired in an operation : viz. that it should be performed, if possible, with celerity and safety. The next thing desirable is, that no unnecessary pain should be inflicted upon the patient. It is upon the latter point, more especially, that appeals to the public are most likely to prove successful ; and it has consequently been the one which has been the most eagerly seized upon by many who have written on the operation for strabismus. The hook for fixing the eye has been invested with " terrors not its own," and its use afterwards described as the infliction of unnecessary pain. The speculum for raising the upper eyelid has been nearly as much abused as the unfortunate hook. That the improper use of either instrument may cause considerable pain I readily admit ; but deny that such is the case if employed with proper care and gentleness. We are told by some gentlemen that the hook and speculum are unnecessary ; that the finger of an assistant will answer the purpose of the one, whilst the other can be dispensed with entirely. It is true that the upper eyelid can be raised very effectually by the finger of a practised assistant : but by persons in general the lid will be better raised by the speculum. As to the comparative pain of the two methods, I have seen both properly managed : and, on questioning patients as to which gave them less uneasiness, the finger or the speculum, the answer has been generally, the latter. The pain caused by the hook has been greatly exaggerated. It would seem that some men delight in raising giants of straw, solely for the satisfaction of easily knocking them down afterwards. It has been asserted that the eye is forcibly compressed by the hook, and that considerable injury is inflicted by the instrument. If the hook be properly made, very slight pressure is sufficient to fix the eye, which has then only to be drawn gently outwards in

the inward squint, without further compression. The hook may certainly, in many cases, be dispensed with; but it is not every one who can so command the muscles of his eye as to be able to keep that organ sufficiently steady without its being properly fixed; and the omission of the use of the hook will, in many instances, not only prolong the operation, but often render the division of the various bands of adhesion incomplete. I believe the employment of the hook will, in a great majority of cases, by facilitating the operation, be the means of saving the patient much unnecessary pain. I have seen the operation for strabismus performed in a great number of instances by Mr. Charles Guthrie, at the Westminster Ophthalmic Hospital, and it appears to me that his method of performing it combines simplicity with neatness and efficiency. In the generality of cases the operation has been completed within a minute; but there have been instances where it was necessary to divide several bands of adhesion, which, of course, rendered the proceeding more protracted. The instruments generally used by him are, a small sharp-pointed bistoury, with a slight curve; a small director slightly grooved upon its concave surface, and sufficiently curved to be passed under the muscle with facility; the hook to keep the eye steady; and small silver speculum. The incision into the conjunctiva is made by inserting the point of the bistoury opposite the lower side of the tendon of the rectus, and cutting upwards for a quarter or three-eighths of an inch. The curved director is then passed under the muscle, which is divided upwards by the sharp-pointed curved bistoury along its grooved surface. If the patient, after the division of the tendon, be capable of directing his eye inwards (or, if an external squint, outwards) in any degree, the remaining bands of attachment are readily caught up by the director, and divided by the bistoury.

This operation should never be considered complete whilst the eye can be turned at all inwards; or, when the squint is in the opposite direction, outwards; for, when all bands of adhesion are fairly divided, the eye usually appears to be fixed motionless in its orbit, with the cornea in its natural position very nearly in the centre. I have never seen a case of strabismus in which it was necessary to divide any other muscles than the external or internal rectus, and cannot help thinking that other muscles have been often cut unnecessarily. It has been said by some persons that the operation leaves the eye in a worse state than the squint for which it was performed; and that it becomes disagreeably staring and prominent. In my own cases no such effect has been produced. I have attentively watched a great many of those operated upon at the Ophthalmic Hospital, and although there has been, in some few instances, a slight degree of increased prominence in the eye, yet it has never amounted to deformity. In the majority of cases, however, the operation has been highly gratifying, and, in many instances, no difference was observed between the eye operated upon and the other. With regard to the number of little hooks that have been invented for fishing up the rectus muscle, I cannot see any advantage they possess over the instrument used by Mr. C. Guthrie, which, by forming at the same time a director for the bistoury, most certainly facilitates the operation. It has been observed in some few cases that, although immediately after the division of the internal rectus the patient has been incapable of directing the eye inwards, yet, in a few days, it has again turned towards the inner canthus. Notwithstanding this untoward occurrence, it has been sometimes found that, in the course of three or four weeks, the eye has again become quite straight. In such a case it is to be presumed that the return of the squint has been caused by effused lymph uniting the posterior part of the divided muscle to the sclerotic coat; and that the subsequent return of the eye to the straight position has either arisen from elongation of the effused lymph, or from the slight adhesions having been broken down by the increased action of the external rectus muscle. When such an occurrence happens, the patient should be made to use the muscles of the eye which has been operated upon by covering the sound one for some little time.

A sufficient period of time has now elapsed since the operation for strabismus was first introduced into this country to enable us to form a tolerably

fair judgment of its success. When properly and efficiently performed, that is, when no bands of adhesion are left undivided, with but few exceptions, the operation will prove highly satisfactory. In Mr. C. Guthrie's pamphlet on strabismus, the results of two hundred cases are stated; and having had an opportunity of seeing most of his patients some time after the operation, I can bear testimony to the extreme accuracy and fairness with which his report has been drawn up.—I am, sir,

Your obedient servant,
ROBERT WADE.

68, Dean Street, Soho,
September 28, 1840.

EXTRACTION OF AN OVARIAN CYST.

BY BENJAMIN PHILLIPS, F.R.S.

[For the Medical Gazette.]

UNQUESTIONABLY it is more agreeable to detail the results of the successful than the unsuccessful practice of our profession; and yet it is equally incumbent upon the practitioner to detail the one and the other: if he suppress successful cases, an unfavourable impression may attach to beneficial practice; if he suppress unsuccessful cases, he is guilty of a serious offence; he may be the culpable instrument through whose agency human life may be sacrificed. There are many surgical operations so firmly established in practice that it may seem unnecessary to publish results; but though this may be true, there is no operation of which we know the precise risk, and therefore all that is exact yet remains to be accomplished. I feel strongly the importance of recording, on a large scale, the risk attendant upon the performance of all operations. It is an element which should be carefully considered before an operation is decided on. For instance, a large aneurismal tumor may exist in the innominata; nature may cure that tumor; it has done so in certain cases: now supposing it could be shown that nature did so once in a hundred cases, and further, that the ordinary operation failed ninety-nine times out of a hundred cases, the operation promises no fairer than nature, and if it fail death is speedy; whilst, if treated carefully, without

operation, life may have been extended for months, or even years: it is clear, then, that under those circumstances the operation would not be justifiable. Up to the present moment we possess neither of those elements so necessary for a proper decision in the case; we do not know whether nature or art be most powerful for good in a large number of cases. If such information be important as regards established operations, how much more so is it as applied to operations about which opinion is divided? Very few of the members of our profession are at all aware of the extent of mortality consequent upon surgical operations; and until a system of reporting is fairly and honestly carried out, we cannot hope to be better informed. An unhappy disposition seems to me to be gaining ground, of publishing only successful cases; as if any moral imputation could attach to failure in cases where failures must often happen. This system is in every respect an immoral one; and that I am not stating the case unfairly must be evident to every one who takes the trouble to turn over the pages of our weekly metropolitan medical journals. I care not what diseases you investigate, if you take the published cases as a fair statement of the results of treatment, you can only come to one conclusion— that the power of medicine and surgery over disease is stupendous; that its failure is uncommon. Take typhoid fever as an example, and you find the mortality scarcely exceeds a fourth, whilst if you take the honest records of an hospital, I care not what mode of treatment has been adopted, and you will find the mortality a full third. Take hernia, take amputation, take the ligature of arteries, and the same reasoning applies. One source of this state of things arises out of a desire men feel to find a cause of death over which they could not have had control; and that is rarely difficult: the consequence of this is, that when they estimate the results of treatment, they exclude all cases where they can find a reason for death independent of the operation or the treatment. This is a dangerous system, pregnant with error, incapable of being turned to good account. It is better that we should know in a given disease (a certain line of treatment being adopted) the wholesale results: so many died, so many

recovered. Short of that there is not, to my mind, any security as to the correctness of our impressions, that one mode of treating disease is better than another. I hope, nay, I am satisfied, that this opinion will ultimately prevail. Several hospital reports have been published within the last year; their example must be followed, because not only the public, but the profession, must be the gainers by the system.

These remarks on the present occasion more particularly refer to a mode of treating ovarian cysts which has been introduced into practice within the last four years. It is not worth while to ransack the archives of antiquity, for the purpose of showing that attempts have, in early times, been made to extract ovarian cysts; for all practical purposes it is sufficient to assume that to Mr. Jeaffreson belongs any merit which may attach to the plan of treating these cysts, by extraction through a small opening in the abdominal parietes. I assume that all cases in which this operation has been performed are before the public. I know only of eleven cases (for I exclude Mr. King's case, in which no cyst was found, though the case did well) in which the operation was performed; of these, seven *perfectly* recovered, one *imperfectly;* she was tapped seventeen times afterwards; and three did not recover: among these I include the following case. Mr. West's unsuccessful case was a patient whose cyst contained eleven gallons of fluid: " her constitution was much shattered," and she had been repeatedly tapped before. A second case occurred in Guy's Hospital; but here the operation was difficult, and the cyst was not extracted: my own is, as far as I know, the third unsuccessful case; and the causes of its failure will be detailed presently. Mr. Jeaffreson has therefore reason to felicitate himself for having introduced to the notice of the profession a mode of treating ovarian cysts, from which, under favourable circumstances, great good may be reasonably anticipated.

There are certain circumstances which are held to be favourable for the success of the operation. A single cyst containing only fluid matter; the absence of adhesion to the abdominal parietes; and a good condition of the general health. Of these the latter is the only one that can be satisfactorily made out; with respect to the first and second we cannot go beyond probable conjecture. However, adhesions, and even the existence of a solid portion in the tumor, are not held to preclude us from the operation; because both have been successfully surmounted.

A. D., aged 21, had tolerably good general health up to last Christmas, when she experienced a heavy, but not intense, pain in the right iliac region; gradually this subsided, and she then perceived a slight enlargement or tumefaction about the umbilical region : this continued steadily to increase, and was accompanied by some pain in the same region. At this time she consulted Dr. Heming, who directed her to lose some blood by cupping; and the pain was lessened. The pain was not at all severe, and was occasioned, in all probability, by distension. In May, the tumefaction was so far increased as to have become apparent externally, and subjected her to remarks which distressed her a great deal. Under those circumstances she stated that in June she applied to Mr. Liston, who referred her to Dr. Locock : he examined her with great care, and told her that she had an ovarian cyst, which then contained probably ten pints of fluid; that it would continue to increase, that medicine would give her no relief, that tapping would afford only a temporary alleviation of suffering, and that, therefore, he would not advise her to submit to it; but that within the last four years an operation had been invented by which the cyst could be extracted; that if it succeeded her disease would be radically cured, and he strongly advised her to undergo that operation. With this opinion she returned to Mr. Liston, who said he would admit her into the North London Hospital. To the hospital she went, but Dr. Thomson, the physician of the week, believing that the tumor was more or less solid, advised that the operation should not be done, and she was not therefore admitted. Thus foiled, but determined if possible to have the cyst extracted, she applied to Dr. Hamilton Roe, who at once detected the nature of the disease, and informed her that she had not the slightest chance of having the tumor removed by medicine or tapping; that her only hope of getting rid of it was

by having it extracted through the muscles of the abdomen; but warned her that though the operation was successful in a majority of those who had submitted to it, nevertheless there was considerable danger, and therefore she must herself make choice whether she would bear to carry about the tumor, with which she might live a long time, or risk her life to get rid of it. He then very kindly referred her to me. After twice examining her, satisfying myself that there had been no peritonitis, that there were probably no adhesions, that her distension was fast increasing, that she was daily becoming less and less capable of getting about, that her health was beginning to suffer, and that she had then probably fifteen or sixteen pints of fluid in the cyst, I reiterated Dr. Locock's advice. I told her what had been the results of the operation, and what were its dangers; I advised her quietly to consider these things, and if, after having done so, she still determined to have the operation performed, I would undertake it, provided, upon consultation with my colleagues, they were of opinion that it was an ovarian cyst, containing only fluid matter. She took very little time to deliberate, but from various circumstances she was not seen by my colleagues for a month: the result of their examination was, that the disease was an ovarian cyst containing fluid, and that it was probably not adherent.

On Monday, September 7, her mother called on me, and it was arranged that she should come into the Infirmary on the succeeding evening, and that the operation should be performed on Wednesday morning. The mother asked me whether she should take any medicine before her admission. I inquired into the state of the bowels, and was informed that they were confined, and that she was constantly obliged to take some rhubarb to induce a sufficient action. I then told her that she had better take on the following morning a small dose of the medicine, so as to gently open the bowels. On Tuesday evening she was admitted into the Infirmary. At ten o'clock I saw her; asked her whether the bowels had acted properly, and was assured that they had. She was in good spirits, and expressed a hope that I would not delay the operation beyond the following morning.

On Wednesday, at 10 o'clock, in the presence of Drs. Roe, Clendinning, Harrison, Hening, and Boyd, Messrs. Samwell, Joseph, Prichard, Brown, and others, I performed the operation. The patient lay on a bed. The first incision commenced about an inch below the umbilicus, and extended rather more than an inch and a half. It was necessary to give the cutaneous incision rather more extent than I at first proposed, because (strange to say, considering how great was the distension) there was three-quarters of an inch of fat upon the abdominal parietes. I dissected, carefully, until I came upon the sac: as soon as I had sufficiently exposed it, I seized it with the vulsella to prevent any difficulty of getting hold of it when emptied. It was then punctured with a trocar, and 320 ounces of a transparent, glairy, albuminous fluid was evacuated: the sac, which was extremely thick, was then drawn out through the opening, which it was necessary to enlarge slightly. The sac had no other attachment than its pedicle; the pedicle was, in fact, the Fallopian tube, to which it was firmly attached over more than an inch and a quarter. Around this tube a ligature was tightly drawn by Mr. Samwell; the ends were cut close, and the sac was detached without the slightest difficulty. Not an ounce of blood was lost during the whole operation; and when it is stated that her heart's action had not been accelerated to the extent of two pulsations during the operation, and that, at the conclusion, the pulse did not exceed 68, it must be evident that the suffering was not great. The external wound was accurately brought together with hare-lip needles, and there was no oozing of blood. From the moment of the operation there was severe pain in the right iliac fossa, which I referred to the strangulation of the tube by the ligature; there was also frequent sickness. To relieve this pain, in an hour after the operation an opiate enema was administered; it produced little relief, and in two hours afterwards a draught, containing thirty minims of the bimeconnate of morphia was exhibited: still the pain distressed her, and in two hours more a pill containing half a grain of the chloride of morphia was administered, and late in the evening another enema, containing forty-five drops of the liquor opii sedat., was

thrown up, and a draught, containing tinct. digital. ♏x.; acidi hydrocyanic. ♏ij.; morphiæ chlor. gr. 1-3d, ordered to be taken every four hours. During the evening, when vomiting supervened, there was an oozing of blood from the wound, but to no great extent.   It was not easy to account for it, because no vessel was wounded during the operation. The only point upon which suspicion lay was the ligature around the Fallopian tube ; but as there was no evidence of blood being poured out into the abdominal cavity, the suspicion seemed vague.

Evening, 12 o'clock.—The pain was still considerable, but mainly referred to the right iliac region ; the general tenderness was slight ; the sickness occasional. The pulse had materially increased in frequency, and the skin was hotter : believing that there was reason to apprehend local peritonitis, I ordered

> R Hydr. Submur. gr. iij. ; Opii, gr. ss. 2ndis horis.   Enema Tereb. statim. Hirudines xx. abdom.

Thursday morning, 8 o'clock.—Pain in iliac region relieved by leeches, but complains of pain in the umbilical region ; tenderness on pressure considerable ; no tympanitis ; nausea still continues ; countenance *very* good, pulse 94; heat of skin moderate ; bowels not opened.

> Ordered to intermit Calomel and Opium ; to rub in Ung. Hydrarg. ℨj. 3tiis horis ; to apply 12 leeches to the umbilical region.

> 12 o'clock.—Bowels still confined.

> Ordered Ex. Col. Comp. gr. ij. ; Capsici, gr. ss. omni hora ; 12 leeches to epigastrium, where she complained of tenderness.

7 o'clock.—Pain much abated ; pulse 100 : bowels still confined.

> Ordered Mag. Sulph. ℨj. ; Acid. Hydrocyanic. ♏ij. ; Tinct. Digital. ♏xij. ; Inf. Rhæad. Comp. ℥ss. ; omni hora.

Friday, 8 A.M.—Bowels acted *well*, three times, during the night ; nausea lessened ; pain much relieved ; countenance good ; pulse 96 ; abdomen soft.

2 o'clock.—Can bear pressure ; has just had a liquid stool.

8 o'clock, P.M.—Has had four liquid stools ; countenance good : complains of pain- probably, from its moving about, tormina ; however, I thought it safer to order—

12 leeches ; Opiate Suppository; Pulv. Aromat.; P. Kino Comp. aa. gr. v.

10 P.M.—Morphiæ Chlor. gr. i.

Saturday morning, 8 o'clock.—Slept from 10 till 3, when she awoke ; more liquid stools ; was seen by the resident physician, Dr. Boyd, who ordered an opiate enema, and Pulv. Arom. and Pulv. Kino, aa. gr.v. : has scarcely any tenderness; abdomen soft. Cholera-like symptoms persist at 12 A.M., when she was ordered to take Cupri Sulphat. gr. 1-3d, omni hora : this was rejected, and Plumbi Superacet. gr. iij.   Ex Paparv. gr. ij. substituted. These were not rejected, but they did not lessen the stools, which were like rice water, and incessant.   Through the whole of Saturday these symptoms continued, without peritoneal tenderness, or any approach to a peritoneal countenance, but with incessant vomiting, the extremities becoming blue, but with the mind intact ; they persisted, without remission, until five o'clock on Sunday afternoon, when she died.

She was examined on Monday (at 2 o'clock) in presence of Drs. Clendinning, Harrison, Lee, and others : the abdomen was soft and flat ; the incised point was nearly healed. When the cavity was exposed, a diffused injection was apparent, but, with the exception of some small patches of lymph, none of the ordinary products of peritonitis existed. In the cavity from six to eight ounces of blood was found ; it contained a few coagula, but it was dark in colour. Upon examining the Fallopian tube the ligature was found in its place ; but it was evident that, from its hypertrophied condition, it resisted the necessary constriction, (although Mr. Samwell had used much force) and the extravasation was a consequence of oozing from the extremity of the tube.   That oozing, however, had long ceased ; for nature had blocked up the vessels.   The opposite ovary was not healthy. Upon laying open the large intestines we found them covered with an exudation such as is found in croup—a false membrane : when this was torn off with a forceps, the membrane presented what the French pathologists term an *erosion*, which was, no doubt, the commencement of extensive ulceration, and which was clearly of some standing.

When the dejections became frequent, the mother of the patient informed me

that her bowels were " very delicate;" that she had forgotten to say any thing about the rhubarb on the morning of Tuesday ; that she recollected it in the afternoon, when her daughter came in ; that the daughter said, " It is lucky, mother, that you did forget it, for I have been twenty times to-day ; but do not say any thing to Mr. Phillips about it, or he will put off the operation."

Although extraction did not succeed in the case of this young woman, it did not, in my opinion, fail from any vice inherent in the operation. I say, without hesitation, that her death was caused by the state of her bowels, and with that I apprehend the operation had nothing to do. I say, with equal confidence, that had this complication not supervened, there is great reason for supposing that the operation would have succeeded. Up to the moment when that cholera-form affection was developed, 56 hours after the operation, the prospect was most cheering ; the abdominal tenderness was greatly abated, the pulse had been reduced to 92, and those who had at first no confidence in the operation, now became sanguine of a successful result. The dangers of the operation, which I had anticipated, were difficulty of getting at or extracting the cyst, the shock of the operation, and peritonitis. In the present case no difficulty was experienced as regards the first two points; and I am fully justified in saying, that the degree of peritonitis was by no means incompatible with recovery. Acute pain followed immediately upon the operation, and continued for many hours : for some time it was a good deal confined to the right iliac fossa, the seat of the ligature, and I was disposed to refer it to the constriction of the ligature ; but I am now inclined to think that it was not produced by that, but was excited by the blood which exuded from the cut surface of the tube : it was at first developed at that point, but as the blood was spread over a larger surface of the peritoneum, the pain was also spread farther. I say I am disposed to adopt this conclusion, though I may have no sufficiently satisfactory proof that blood in contact with the peritoneum will at once excite severe pain. I have only two cases to adduce in proof of such an effect :—one was an aneurismal tumor, which had burst into the cavity of the peritoneum; the pain was immediately dreadfully

intense : in the other case, the spleen was ruptured by a fall : immediate agonizing pain was developed all over the abdomen : about six ounces of blood were found in the peritoneal cavity. In opposition to this opinion, I know that Mr. Gulliver has injected blood into the abdominal cavity, without out exciting inflammation, or apparently pain. In our case the ligature had excited no peritonitis ; the blood had, but it was not intense, though diffused ; the early and energetic treatment employed had prevented its further development, had induced it to enter upon a retrograde course : this, I submit, is proved by the great abatement of pain, the lesser frequency of the pulse, the relief of the sickness, the absence of tympanitis, the ability to lie perfectly straight without inconvenience, the character of the face, and the occurrence of three good stools. The blood had ceased to ooze : the inflammation produced by that which was extravasated was fast abating, and the ligature had not proved itself apt to excite peritoneal inflammation at all. I say, then, that so far as the operation is concerned, it afforded, in the present case, a fair and probable cause to believe that it would have succeeded, if we had not had to contend with the supervening affection.

My confidence in the operation, when there is reason to believe that there are no adhesions, and that the patient's health is satisfactory, is greater than when I undertook it in the present case : and when we take into account the results of medicine, of tapping, or of the disease left to itself, I think no one can doubt that an operation which, under adverse circumstances, has succeeded nine times out of twelve cases, ought to be resorted to, before complications or counter-indications are developed. We do not hesitate to have recourse to the ligature of large arteries, and to regard it as a justifiable operation, though the results are much less favourable ; we do not object to perform amputation of the thigh, although nearly two out of five die ; and why should we regard an operation exhibiting such a result as is presented by the operation of extraction of an ovarian cyst with disfavour ? Simply because it looks formidable, and because it is new. But it may be said the difficulties are frequent, adhesions almost always occur, and they must materially

lessen the chances of success. I know Dr. Seymour has stated that these adhesions exist in 99 cases out of every 100. I am by no means prepared to contradict the correctness of this assertion, because my opportunities of examining these sacs after death amount only to nine cases: in several of these the patient had been tapped, but in not one of them did the cyst adhere, except by its peduncle, whose extent was variable, though never great. In twelve instances the results of the operation of extraction are recorded; of these there were adhesions in four cases, and in two of them the patient had been tapped; but in neither of those cases did the adhesions constitute a serious obstacle to the removal of the cyst. It may be said that another difficulty may be experienced, by the presence of more than one cyst, and the occurrence of a considerable quantity of solid matter. That more than one cyst may exist in the same tumor at the same time cannot be denied; but although it may be, it rarely is presented; and there can be no difficulty in introducing the trocar into the second cyst, if it be found to constitute an obstacle to extraction. As to the coexistence of a large cyst and a solid tumor, I do not deny that it may happen, but I do maintain it to be a rare exception; and if that rare and exceptional case is presented, the practitioner should be prepared to meet it. In my apprehension the occurrence of peritonitis is the danger; but that is a danger which we do not regard in the same light in other cases. The opening into the abdomen is not much larger than that which is made in cases of hernia. But it may be said peritonitis very commonly follows that operation. In my opinion it more frequently precedes it; the symptoms commonly presented warrant me in coming to that conclusion. But recollect, in the one case we have at the time of operation (for we can choose our time) a comparatively healthy abdominal cavity; in the other we have a greatly injured intestine, and a probably inflamed peritoneum. I believe, in the present day, the operation for hernia has such unfavourable results, because we wait too long—until, in fact, peritonitis is developed; that we too energetically manipulate the part: this is first done before a patient is admitted into an hospital, then by a house-surgeon, then perhaps by an assistant-

surgeon, and lastly by the surgeon himself. Add to this, that irritating injections and drastic purgatives are often given, and how can we conceive it to be possible that the patient should escape scatheless? The result of this practice might be anticipated. In the hospitals of Paris it is estimated that half of the patients who are operated on for hernia die; in London I believe the results to be little more favourable. I believe, when done at a proper time, the operation for hernia is a very successful one, though I do not go so far as Pott, who maintained that, when undertaken at a proper time, there will not be more than one death in fifty. If after the operation for hernia, the gut not being too much diseased, and the peritoneum not being inflamed, the mortality consequent upon the development of peritonitis be three times as great as Pott believed it to be, still it would constitute a very small mortality; and if we say that, in the operation we are considering, the chances of peritonitis were four times greater than in hernia, still it is clear that we ought not to hesitate, when the patient's condition is favourable, to perform the operation of extraction of the cyst.

MEDICAL GAZETTE.
Friday, October 9, 1840.

THE MEDICAL SCHOOLS.

WE believe that the whole number of medical pupils who have this session entered at the Metropolitan Schools is considerably less than it has been for some years past. A gradual but slow decrease has been observed for several sessions, as the result of which we have noticed the closing of some of the smaller schools; but this year the diminution of the number of students is more considerable, though the loss, having fallen in nearly equal proportions on all the schools, is not materially felt by any of them.

Many circumstances may be assigned

as the causes of this change. The alterations made in the scheme of education required by the Apothecaries' Company a few years since, and the fears that other changes would soon follow, of which the tendency would be to render the attainment of the license still more tedious and difficult, might induce some students to repair very early, not to say prematurely, to London, that they might be secured from the effects of alterations made subsequently to the date of their entrance to lectures. Thus, while there would be an excess in the pupils of those years, there might be expected a comparative deficiency of those of the present. And in the same manner the unsettled state of the regulations of the College of Surgeons may be supposed to have exerted a similar influence; or, still more, their late arrangement, by which candidates for the diploma are not required to have received any part of their medical education in London, may be believed to have already operated to the disadvantage of the London Schools. It may be that each of these circumstances has had some influence; but we are assured that the falling off, not only in this, but in several past years, is greater than can be accounted for by any or all of them. The influence of the two first of them would, indeed, necessarily have decreased in the last two years, and that of the last of them would scarcely yet be felt; for there is at present so strong an opinion (whether well-founded or not) of the advantage of attending the London Schools and Hospitals, that none will yet be inclined to forego them, except those who, if the above-mentioned regulation had not been made by the College of Surgeons, would have educated themselves for the Apothecaries' Hall in the country, and would not have taken the diploma of the College at all.

We feel assured that the cause of the decrease of London students has a much deeper origin, and that it is only a sign, though the best that can be afforded, that the whole number of persons entering the profession of medicine is annually becoming less. That this is the case is strongly confirmed by the reports which are constantly received from the provinces of the difficulties which practitioners find in obtaining apprentices even at reduced premiums, and by the consequent demand for assistants. Between ten and twenty years ago every surgeon in the country who enjoyed a moderately extensive practice had his one or more apprentices, by whom all the dispensing and minor visiting was performed, and who, for the advantages of these, and a certain amount of medical instruction, paid a handsome premium. Now, surgeons can often get no apprentices at all on such terms, and must be content either to do all their work themselves, or to take an apprentice whose money-premium is merely nominal, and who actually pays by his services alone, or they must (as the large majority do,) take an assistant, for whose services they themselves have to pay.

The number of well-educated members of our profession—gentlemen by birth and by attainments—who are now compelled thus to earn their maintenance as assistants, is, indeed, truly lamentable. We can almost remember the time when no such class existed. The Apothecaries' Assistant of the Bill of 1815 was a person of altogether a different caste, educated in an inferior manner, and not licensed to practise for himself, holding an intermediate rank between the regularly licensed apothecary and the druggist. In the present day, unhappily, the place of the Apothecaries' assistant is too often occupied by the apothecary himself; by one well calculated to undertake all the charge of the practice, of which

he is compelled to do only the inferior work.

From all this, as well as from many other circumstances to which we have often called attention, it is evident that the number of medical practitioners is, at the present time, too great for each of them to be adequately remunerated. The number of persons entering the profession will always be determined by the probability which their parents or guardians can see that money will be well invested in medical education. Now the tendency of late years has been (very properly) to raise the standard of professional knowledge; but this could not be effected without at the same time, and in nearly the same proportion, adding to the expense of attaining it; and unfortunately, there has appeared no promise of increased remuneration to compensate for this increased outlay. When parents see those who are fit to be practitioners leading the weary life of assistants, always ill paid, and often utterly unable to find an opportunity for such an exertion of their energies as might lead to an improvement in their condition, no wonder if they hesitate to expose their sons to the risk of such a fate, and instead of committing them to the chances of medicine, send them to the less exhaustible sources of profit in other professions, or for the certain remuneration of industry and talent which is promised in almost every branch of commerce.

The decrease of students in London, then, is only another proof of the fact that the profession is already, and has been for some years, *overstocked*, by showing that medical education is no longer considered by the respectable part of the public a good investment for their money. It is the misfortune of both the practitioners and teachers of this generation that they have fallen on the days when the evil has so accumulated as to have begun to work

its own cure. That it will do so cannot be doubted; the supply of medical practitioners, as of everything that is required for the public service, must be guided, or rather must guide itself, according to the demand made for them; and of this demand the measure may always be ascertained by the degree in which each is remunerated.

The present excess has resulted from numerous causes in combination. The cessation of the war not only immediately added largely to the number of practitioners resident in the kingdom, but by cutting off the anticipated source for the employment of a still larger number, who were then pupils, compelled them also to seek for practice in some other field than that to which they had destined themselves. The army and navy have since been comparatively closed to the profession; the number of surgeons required for the service of either has borne no proportion to the number that could, with profit to all, have been supplied. The new colonies again, to which such multitudes of all occupations are annually flocking, and by which so many of the various trades in the mother country are relieved of their superabundant supply of hands, are of comparatively little advantage to the members of our own, and the other professions; for at present the wide extent of country over which the settlers are scattered, and the insufficient remuneration that they can offer, render it barely possible for any considerable number of medical men to obtain a profitable practice; and hence the greater number of those whom we have known going out to Australia, New Zealand, and other parts, have contemplated resigning their profession (except for domestic purposes), and engaging in some of the staple trades of the colony. Again, and which is perhaps of yet more influence, the druggists, whose numbers have of late years increased

so greatly, are now, almost to a man, medical practitioners, and occupying almost precisely the situation which was filled by the majority of the apothecaries anterior to the year 1815. They engross the greater portion of what, though it is called small practice, has always produced large profits. Add to this, the amount which is annually expended in the constantly increasing dispensaries (of which it may be fairly calculated that at least three-fourths was formerly paid to medical practitioners), and some idea may be formed of the decrease of the profits which our profession has suffered.

It may be, as we have said, a consolation to the present race of practitioners to know that the evil is now curing itself, and to be able, by the evidence of the decreasing number of students, to assure themselves that at least the younger members may expect to see better days. The medical profession must always be sufficient to give its members a certain rank in society; in short, to make those of them, whose conduct does not neutralize its benefits, gentlemen. It cannot, therefore, ever cease to be a desirable profession for those whose means are sufficient to enable them to live for a time with but small remuneration for their educational expenditure. The increased expense of education, and the smaller profits of practice, therefore, will have less influence than might be expected on those whose association will be the most honourable to the profession : and that this is the case is proved by that which we have long observed, and which the public are now readily acknowledging—we mean the remarkable superiority of the medical students of late, over those of former years.

MR. WARBURTON'S BILL.

Our readers will, we doubt not, do us the justice to admit, that our estimate

of Mr. Warburton and his organs of legislation has been correct throughout. From the beginning, as the pages of this journal show, we scouted the idea of his ever doing any thing that would prove satisfactory to the profession; and while certain of our contemporaries, who have now at length thrown him overboard, were lauding him to the echo, we, and for a long period we alone, denounced his proceedings, and ridiculed the idea of his having either the will or the talent to benefit the members of our profession. Well, after a most memorable Parliamentary Committee—after an immense expense and great delay—after expectations often raised, and hopes as often deferred, at length, just at the close of last session, a bill was actually introduced—too late, indeed, to do more than just secure its being ushered into the world—under the auspices of Mr. Warburton, Mr. Wakley, and Mr. Hawes. Such was the eagerness to forward it, that the ordinary forms were overstepped, to secure the speedy delivery of the progeny which had been so many years in the incubation. And such a progeny—such a crude, deformed, ill-favoured abortion, at the end of seven years' gestation, that all who have looked upon it, friends and foes alike, unite in their expressions of abhorrence. A pretty specimen, assuredly, of liberal legislation, for an honourable profession to have laymen to control them in their governing body, and the minister of the day to regulate and supervise the expenditure of their funds ! The plan altogether is more preposterous and absurd than those who have not studied it can imagine, and it might be very truly designated, " A bill to incommode, degrade, and oppress the regular members of the medical profession, and give support and encouragement to quackery." And this comes at last of all Mr. Warburton's labours, and cogitations, and

procrastinations. Never was the hackneyed quotation, "parturiunt montes," &c. more entirely applicable, if we regard the value of the produce; though, if we reckon the quantity of foolscap, the estimate must be something different.

As we have said, all parties are equally disgusted with it—even Mr. Wakley, who lent his name to the bill, which he is now most anxious to assure us he had never seen, affrighted by the shout of indignation with which it has been received, has thrown his friend overboard, and now eagerly joins in the cry against him. He attributes all the tyrannical folly of the bill to Mr. Warburton's having formed his opinion of the profession at large from the medical corporations. Nonsense: Mr. Warburton is not so great a fool as his ci-devant coadjutor would make him. He examined both sides of the question, and men of all parties, on his most tedious, and, as it now proves, most useless committee—nay, he paid the chief attention to those who were hostile to existing institutions. Tell us not, therefore, of his being misled. No, no; the bill is fairly to be taken as the estimate of the medical profession formed by Mr. Wakley's friend, the honourable member for Bridport, who proposes that we shall be taxed to purchase chains for ourselves; that laymen be introduced into our governing bodies; and that the expenditure of our funds, raised by a new and extraordinary exaction, be regulated by the minister of the day!

We end as we began, by declaring, that low as our estimate of Mr. Warburton, in reference to his legislation for us, has ever been, and openly and freely as we have always declared this, the present bill exceeds in folly and oppression any thing we had anticipated; and if passed, (of which, thank heaven, there is not the slightest risk),

would surpass in tyrannical folly any modern specimen of legislation with which it is our lot to be acquainted.

DIABETES MELLITUS.

Iodic Acid as a Test of Uric Acid. Exciting Causes and Pathology of Diabetes. Existence of Sugar in the Blood and various Secretions. Treatment. Apparent benefit from the Nitrate of Silver.

Henry M'Ewan, admitted on the 21st of December, 1839, ætat. 25: weaver, small, thin, and lax in his habit of body. Complains of general debility, dragging pains in his back and loins, weakness and coldness of lower extremities, and occasional headache. Is much troubled with a voracious appetite, urgent thirst, uneasiness about the stomach, and frequent calls to void urine. Urine passed generally amounts to about fifteen pounds daily, has a saccharine taste, is of a pale colour, and of sp. gr. 10·38. Tongue white, bowels regular, skin dry, pulse 90. Has been ill nine months, and was on two occasions relieved by large doses of opium and animal diet.

This case is characterised by the usual diagnostic symptoms of the disease, viz. great thirst, increased appetite, emaciation, lassitude, weakness in loins, greatly increased secretion of urine, which has a high specific gravity, and contains a large quantity of saccharine matter. The urine, when newly passed, is quite limpid, has a greenish hue, reddens litmus paper, and has a faint peculiar odour; not, however, like new hay, as has been described by some authors. It is very saccharine to the taste, becomes pale and opalescent on standing for some hours, and ferments briskly on the addition of yeast. No precipitate is thrown down from it, by heat or nitric acid. Its sp. gr. has ranged from 10·31 to 10·40, and the amount has varied from twenty-three to twelve pounds. The extract which is furnished by the evaporation of the urine, with an ordinary heat, is dark coloured, very sweet, and amounts to 39½ grains in 500; but when the steambath is employed, and the evaporation conducted slowly, it assumes a granular form, and is whitish. The chemical constituents of this urine, with respect to urea, has not been examined, as there seems no reason to believe that it differs from that of other diabetic patients; but as the amount of uric

acid in mellitic urine has not hitherto been so much investigated, we tried iodic acid as a test for this constituent. Iodic acid is well known to be decomposed by morphia, and is generally described by chemical authors as a test for this proximate principle; but it is also decomposed by uric acid, as we have stated in the MEDICAL GAZETTE. It is mentioned by some writers on diabetes that though the other saline constituents exist in the usual proportion, there is an invariable deficiency of uric acid in the urine of diabetic patients; and as the ordinary method of detecting uric acid in diabetic urine by means of nitric acid is rendered obscure, if not fallacious, by the presence of saccharine matter, the iodic acid was employed.

When iodic acid and gelatinous starch, recently prepared, are added to healthy urine, and agitation employed, in a short time, but varying according to circumstances, the odour of iodine is disengaged, and a pretty deep indigo-blue colour and precipitate are produced. When iodic acid and starch were added to the urine of our patient, no change of colour was observed for about a week; but after that period the fluid became slightly brownish, then purple, and, in the course of about a fortnight, it assumed a deep-blue colour, and deposited a similar precipitate. When some of this urine was fermented, so as to destroy a considerable portion of the saccharine matter, the action of the iodic acid was much more rapid; and in order to show still farther the influence of this principle, we mixed equal parts of healthy and diabetic urine, and added iodic acid and starch to them, but no change of colour was observed for nearly a week, after which period the blue colour and precipitate were rapidly developed. It appears, from these experiments, that the reaction of the iodic acid is retarded by the presence of saccharine matter in the urine, but that it is still available as an excellent test of the presence of uric acid in this fluid, provided sufficient time be allowed for the production of the change, or the sugar be previously decomposed by fermentation.

Exciting causes and seat of the disease.— The cause or causes which excited the disease in this patient are not known, but he ascribes it to working in a damp shop. It was accompanied, in its early stages, by derangement of the digestive organs, viz., acidity, eructations, constipation, &c., as it is frequently in many other cases; but although it is probable that these symptoms preceded the formation of saccharine urine, there is no evidence existing on this point, as he does not recollect any thing particular, except being weak, unwell, and of having frequent calls to pass urine.

The pathology of diabetes is involved in almost perfect obscurity. Its seat has been referred alternately to the kidneys, and to the digestive organs, and by some authors to both; and although the first organs have frequently been found in a hypertrophied or other morbid condition, yet, in a certain number of cases, they have been found perfectly normal, evidently proving that organic disease in them is not an anatomical character of the disease. And we have frequently found the kidneys in a morbid condition in inspections of typhoid patients, where no disease, connected with the urinary organs, existed. We believe that the stomach has been still less frequently found in a morbid state, so that, as far as pathological investigations can throw light upon this disease, we are utterly in the dark. It is important, however, that we form some theory respecting the seat of the disease, if it can be grounded on facts and experiments; for though it may not, at present, enable us to treat it more successfully than was done during the time when its chemical history was more imperfectly known, still it may ultimately lead, either to the employment of some agent of a curative nature, or to some prophylactic measure where the disease may be expected to occur, as there is reason to believe that it is sometimes hereditary. Where, then, is the seat of the disease? Is it in the digestive organs, the kidneys, or lungs, or in all of them? It has of late been rendered extremely probable that the disease is intimately connected with a peculiar derangement of the assimilating organs. These have, in a great majority of cases, been palpably affected, and generally the disease occurs in persons of a dyspeptic habit of body. This being a far more constant concomitant of the affection than any other symptom, except the saccharine state of the urine, tends very much to support this view. Mr. M'Gregor, of Glasgow, has shewn that both in healthy and in diabetic persons, fed upon a vegeto-animal diet, sugar is contained in the contents of the stomach; and he deduces this conclusion from experiments, in which the contents of the stomach were evacuated by an emetic, and were afterwards briskly fermented by the addition of yeast. Mr. M'Gregor also fed healthy individuals with roast beef and water exclusively, for three successive days, and found, at the end of this period, that the vomited matters gave no signs of fermentation; but when the same treatment was adopted in two diabetic patients, he found that fermentation was produced in the contents of the stomach, on the addition of yeast, though not so briskly as in his former trials. These experiments are very important, and tend very strongly to prove the extensive formation of sugar in the stomachs of diabetic patients; but it would, in our

opinion, elucidate this point still further, were the author to extend his experiments to an' ordinary dyspeptic stomach ; for certainly fermentation very frequently occurs in the contents of that organ when it is functionally or organically diseased, as is indicated by the formation of acid and disengagement of gas. And if it should be found that even animal food underwent a species of fermentation with yeast, after it had remained a certain time in a stomach functionally deranged, the conclusion would be nearly inevitable that it was not merely the formation of sugar in that organ that was the cause of the diabetic phenomena. Mr. M'Gregor's experiments, however, when coupled with the fact that the blood, in diabetic patients, contains sugar, tend very strongly to prove that the assimilating functions, and not the kidneys, are at fault in this disease—at least as far as the formation of sugar is concerned. Sugar has been shewn to exist in the blood of diabetic patients by Ambrasiani, Rees, Maitland, &c., and Mr. M'Gregor has confirmed these experiments by the production of fermentation in the serum of this fluid. In the Journ. de Chimie Medicale, for December, 1839, there is recorded an analysis of diabetic blood and urine by M. Müller, of Madebach. In twelve ounces of the former he found one drachm five grains of sugar ; and in fifty ounces of the latter two ounces three drachms, and thirty-seven grains. Mr. M'Gregor has also detected sugar in the saliva and excrementitious matters of diabetic patients, and even traces of this substance in the blood of healthy persons, when fed on vegetable diet. If, then, it be proved that sugar is formed in the stomachs of both healthy and diabetic persons, who feed upon a mixed diet of animal and vegetable food, how does it happen that sugar is found in such abundance in the blood and urine of the latter ? Is it the superabundance of the sugar which renders its total conversion into chyme or chyle impossible ? or is the diseased stomach incapable of assimilating sugar in any proportion ? This question cannot be solved in the present state of our knowledge ; but it is highly probable that, if sugar be at all capable of assimilation, it is only in a small proportion ; for the quantity of it which is discharged by the urine in twenty-four hours is sometimes enormous. Indeed, the assimilating powers of the digestive organs over animal food must also be very small ; for patients are not found to increase materially in weight upon this diet any more than upon one mixed with vegetables ; and unless we suppose that the whole of its nutrient principles are converted into sugar, which is by no means probable, its assimilation into pure chyle must also be accomplished in very small quantity. And

It has been found that, though animal diet often diminishes the formation of sugar to a very considerable extent, yet that the amount of urea is always uniformly increased, though not on account of the decrease of sugar, as has been conjectured. The quantity of urea passed by a healthy individual daily, according to Mr. M'Gregor, may vary from 362 to 428·5 grains ; but in some cases of diabetes he has found it amount to 1013·5 ; the sp. gr. of the urine being 1039, even when the patient had been subjected to no treatment. This fact tends to show that more of the nutrient principles of animal diet are carried out of the system, in the form of urea, than in health, unless we suppose that, in all the cases in which this excess was found, double or treble the usual quantity of *nitrogenated* food was consumed.

It is maintained by some authors that this superabundant quantity of sugar in the blood acts as a poison to the system, and hence induces the fatal termination which almost uniformly follows this disease. This hypothesis is very plausible, and certainly can be supported by very cogent and analogous arguments, as it has generally been found that foreign substances introduced into the blood, however bland, induce disease or death in the animals experimented with ; but if it does act as a poison it is undoubtedly extremely slow in its operation. But if we suppose, as stated by Mr. M'Gregor, that healthy blood contains a small portion of sugar, the circulation of a certain amount of this ingredient will be quite compatible with health ; therefore it will not be so obnoxious or deadly, in an increased proportion, as if it were totally foreign to its constitution, and may, consequently, require a much longer period to effect its fatal influence. But another hypothesis may be brought forward, capable also of being supported by very cogent arguments, viz., that diabetic patients sometimes die of inanition. The quantity of saccharine matter which is daily evacuated from the system, without contributing to its support, is very great, and there must be left a very small portion of nutritious material to supply the wear and tear of the system. Thus, suppose that a pint of urine (as Dr. Henry has established), of the average sp. gr. 1040, contains 1 oz. 4 drs. 2 scr. 6 grs. of solid extract, 20 pounds of such urine will contain about two pounds of solid extract, a large proportion of which is saccharine matter. The appearance which the patient assumes, in the latter stages, tends to support this view, viz., his emaciation, feebleness, hollow countenance, &c. At the same time it must be acknowledged that both the views we have given are quite hypothetical, and neither may individually account for all the facts connected with the history of the disease ; but if the two theories

be conjoined, that is to say, if both the poisonous effects of the saccharine matter and the defective nutriment of the system be taken into calculation, the view will be sufficient to account for the fatal termination, although it is possible that future discoveries may throw an entirely new light upon this subject.

Treatment.—The treatment of this disease may be included in the following catalogue of remedies, viz. 1st, animal diet ; 2d, opium ; 3d, diaphoretics ; 4th, bleeding ; 5th, astringents. In the treatment of our patient, we have chiefly employed the three first, viz. a diet composed chiefly of animal food, opium, and diaphoretics, including the warm bath. His daily diet, at present, consists of 38 ounces of milk, 12 ounces of soup, without vegetables, 10 ounces of bread, and 18 ounces of steak. On his admission he was treated with four grains of opium and half a drachm of Dover's powder daily, along with the warm bath every second night. This treatment did not, to any great extent, diminish the amount of urine, and on the 31st of December the opium was increased to eight grains, combined with a little calomel, which affected his mouth in about ten days, with diminution of the urine from 21 to 15 pounds. As soon, however, as the effects of the mercury disappeared, the amount increased, although the quantity of opium was the same as when exhibited along with the mercurial.

Some time ago, we observed in the MEDICAL GAZETTE a formula by Dr. Todd, which he proposed to employ in cases of dyspepsia, viz. an artificial digestive fluid, prepared from rennet or the fourth stomach of a calf. Having formed the opinion that the proximate cause of diabetes was intimately connected with the digestive process, we considered it a fair experiment, to test its power upon a patient affected with this disease. We could not procure the fresh stomach of the calf at the time ; but received a sufficient supply of salted rennet, such as is used by farmers for coagulating milk. This appeared to us likely to contain a sufficient quantity of gastric juice for a trial. The following is the formula :—

℞. Rennet, 6 grs. ; muriatic acid, 6 grs. ; water, ℥ij.

Half an ounce of this infusion was at first taken daily after meals, diluted with seven or eight times its weight of water ; and the quantity was afterwards increased to one ounce. He continued this preparation for several weeks, but it seemed to have no effect in diminishing the quantity or saccharine contents of the urine. We tried the same infusion made with fresh rennet, in the case of a patient in ward No. 3, with nearly the same results.

Having thus failed in producing any impression on the disease by this agent, he was finally treated with the following mixture :—

℞. Tr. Opii., ℥j. ; Vin. Ipecac., ℥ss. M. Cap. ℥j. ; 6ta. quaque hora.

His diet was also reduced to the following : 24 ounces of milk, 16 ounces of steak, 12 ounces of bread. Under this treatment for about three weeks, his urine was reduced to about twelve pounds on the 29th of February, when he left the hospital. We have no doubt that the amount of urine, in this case, might have been much more diminished, if the quantity of opium had been increased, such as to 30 or even to 60 grains in twenty-four hours ; for it has been ascertained, by repeated experiments, that large doses have diminished the amount of urine to its natural quantity, or even below it ; but its specific gravity is not diminished by such treatment, and, on the contrary, is often increased. There is generally also a great increase of urea, which is sometimes capable of being crystallized, simply by the addition of nitric acid to the urine, and which, being decomposed in the bladder, may give rise to the formation of carbonate of ammonia.

These large doses of opium have scarcely ever produced any permanent cures, and they are attended with very considerable risk, by the production of inflammatory action in the chest, such as pleurisy. And even though inflammation should not be produced, the patient is left so exhausted, after the use of it (from its injurious effects) that he is more likely to sink from exhaustion.

We have used a combination of opium and nitrate of silver in two cases, with considerable diminution of the quantity of urine. M. Fleming was admitted on the 10th of March, 1840 ; his urine was very saccharine, and varied in specific gravity from 1030 to 1038. He was treated with the warm bath, Dover's powders, rennet, &c. but with very little effect ; notwithstanding that he perspired very copiously during this period. He was put on the use of the following pills on the 27th of May, when his urine was about 20 pounds, and was dismissed on the 23d of June, with it reduced to 13 pounds.

℞. P. Nit. Argent. ℥ss. ; P. Opii. ℥j. M. Fiant pilu æ lx. Cap. j. 6ta. q. q. horâ.

Another case, viz. James Dick, admitted on the 14th of February, 1840, with severe dyspeptic symptoms. A pill, composed of three quarters of a grain of nitrate of silver, and one grain of opium, was prescribed every sixth hour ; which he afterwards took six times a day. His urine was about 20

pounds on his admission, and when dismissed on the 4th of April, it was reduced to 11 pounds.

A diet consisting chiefly of animal food is perhaps the most important part of the treatment ; for the saccharine matter, which is formed from it, is greatly less than what is formed from vegetable food ; and this must diminish the injurious effects, which no doubt result from a large quantity of this principle circulating in the blood, even although the patient do not derive much more nutriment from it than from the other.   At the same time, we are of opinion that, like opium, this plan of treatment may be pushed to an extreme ; for it has been established, that a diet consisting exclusively of animal principles, will occasion, in a longer or shorter time, disease in the system, which may ultimately prove fatal.   It is, therefore, the safer course, to combine with the animal diet a small portion of vegetable food, such as does not readily run into the acetous fermentation, of which bread, rice, arrowroot, sago, &c, are the best.

[To be continued]

PROVINCIAL MEDICAL ASSOCIATION—EASTERN BRANCH.

The annual meeting of this society was held at Bury St. Edmund's, on Monday last, The meeting for transacting the business of the society, and for hearing read whatever essays might be contributed, was held at the Guildhall, at 12 o'clock.   Mr. C. Smith was unanimously called to the chair.

The report, which was read by the Honorary Secretary, Dr. Crosse, contained a very favourable account of the state and prospects of the Association, and a strong appeal to the members in favour of the effort to procure medical reform by legislative measures.

Papers were then read on the following subjects : — Mr. Ewing en chronic laryngitis, Mr. Copeman on bleeding in apoplexy, Dr. Arnold on an improvement on the stethoscope, by substituting metal for wood, the latter being a bad conductor of sound, and affected by atmospheric influence ; Mr. Nunn on dysphagia ; Mr. Crosse on a case of prolapsus linguæ, in illustration of which several plaster-of-Paris models of the protrusion were exhibited, with a sketch of the internal portion of the jaw ; and Dr. Hake on ossification of the various kinds of calcareous deposits.

Ipswich was appointed the place for the next meeting of the society.

Mr. Jefferson wished to make a remark or two upon a clause in a recent act of Parliament for the extension of vaccination.   It was intended, and would have the effect of compelling medical men, who were Union surgeons, to vaccinate all those who might choose to apply to them, for the charge of 18d. : this he thought was degrading to the profession. He was perfectly willing to extend vaccination, and to perform it upon the poor for an 18d. fee, but he did not like to do it for his regular patient, the little tradesman or the little farmer, who would then be entitled to demand it.   He wished very much to have the sense of the meeting upon the subject.

Mr. Young thought the intention of the legislature was that the poor should have the opportunity of going to a medical man, and being vaccinated for that fee, but the act never could contemplate that those who could afford to pay a larger amount should demand to be vaccinated for that sum.

Dr. Bree said the sum allowed under the Poor Law Act of Elizabeth (half a crown) was barely sufficient to remunerate a medical man in tolerable practice for two attendances, and for dispelling the prejudices from the minds of the poor.   When he first received the situation he held as surgeon to the Union he offered to vaccinate any poor person who should apply to him, gratis, simply because he wished to shew that he was friendly to the protection afforded by vaccination.

Dr. Crosse thought the amount of remuneration proposed by the Poor Law Commissioners for vaccination was quite as good as in any other department of pauper attendance, and he really hoped that no respectable patient would take undue advantage of the 1s. 6d. fee.   He would propose (which was carried) a resolution that a committee be formed, to consist of Messrs Jefferson, Day, and Bree, to hold communication on this subject with Mr. Chadwick, the Poor Law Commissioner, who had the sole direction of these matters.

After thanks had been voted to the Chairman. the meeting adjourned, to dine at the Angel.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, *Latitude* 51° 37´ 32´´ N. *Longitude* 0´ 3´ 51´´ W. *of Greenwich.*

On the 30th ults. clear ; the 1st inst. and morning of the 2d, cloudy ; afternoon of the 2d, and following day, generally clear ; a few drops of rain on the evening of the 3d ; the 4th generally clear, rain at times ; the 5th morning cloudy, otherwise clear, with rain ; the 6th generally clear.

Rain fallen, ·055 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture IV.

Morbid alterations of the fluids, especially of the blood. Changes in its quantity and distribution. General and local plethora. Poverty of blood. Active congestion—its phænomena—state of the vessels as seen by the microscope. Mechanical congestion. Passive congestion. Relations of these forms of congestion to inflammations — to hæmorrhages — to dropsies.

After running over the principal alterations to which the solid parts of the body are liable, we were beginning to enquire into those no less important morbid changes which are apt to take place in its fluid constituents. I reminded you that, respecting the whole of this subject, pathologists had passed from one extreme of opinion to another : that for a very long period the *humoral pathology* prevailed in the schools, and that in times not very remote from our own it was entirely superseded by the opposite doctrine of exclusive *solidism*. It is strange that either misconception should have so long maintained its ground.

If we consider the definite relation subsisting between the solids and the fluids of the body, and the unceasing agencies which they mutually exercise on each other—how, for instance, on the one hand, all the solids are originally built up, and are afterwards perpetually nourished and sustained by materials furnished from the blood—how, again,

on the other hand, some of the solids are c ntinually employed in the reciprocal office of feeding and renewing the blood, while others are as constantly busy in decompounding it by the various secretions—we cannot avoid perceiving that distinctions of the kind I have mentioned, founded upon mere differences of consistence, are futile ; that no notable alteration can take place in the solids of the body which will not soon affect in some way its fluids ; and that every important change in its fluids must lead to a corresponding and proportionate modification of its solids : in fine, that the dispute between the solidists and the humoralists was altogether baseless and unprofitable.

The animal fluids are—the blood, the fluids that enter the blood, and the fluids that proceed from the blood.

The fluids that enter the blood are of two kinds.

1. Those by which it is renewed and enriched.

2. Those which enter it in order that they may be conveyed out of the body.

Now although we cannot doubt that any considerable modification of the fluids that feed and renovate the blood, and particularly of the chyle, must have a direct influence upon its composition and quality, we really know but little about them, except in their effects. We seldom have any means of procuring these the first products of nutrition, so as to examine them, or to test their qualities. Yet we can perceive causes that are likely to deteriorate or deprave those fluids (unfit aliment, impure air), and we know that under the continued operation of such causes, the blood, replenished by these fluids, *is* actually and sensibly modified.

Again, we cannot doubt that some of the matters derived from the body itself, and taken into the blood in order to be conveyed away, may, and often do, directly alter and contaminate the blood, and act as poisons upon the system : matters, for instance, ab-

H

sorbed from parts of the body that are diseased, or dead and putrefying ; in this way, doubtless, disorders which were at first strictly local may come to affect the whole economy : — matters, again, which though harmless in minute quantity, become noxious when retained and accumulated in the blood, in consequence of faulty or deficient action of the organs destined to eliminate them from the circulating fluid. The injurious effects of some of the substances which thus become deleterious — as urea, of which the blood, during health, is continually purified by the kidneys, and bile, which is naturally separated therefrom by the liver, and carbonic acid, which it is the office of the lungs to excrete—will furnish topics of interesting enquiry hereafter.

The fluids that *leave* the blood may be considered under a threefold division.

1. Those which are directly expended in the growth or maintenance of parts, some of them becoming fixed and solid, and others retaining their fluid condition. Of these the principal alterations have been briefly pointed out among the *lesions of nutrition*.

2. Those that are employed in aid of some definite function of the body : as the saliva, the gastric juice, the bile, the pancreatic secretion, the tears, the synovia of the joints, and so on. Now these may be secreted in excessive abundance, or in too scanty quantity, or of imperfect quality, or not at all : — and all, or any, of these deviations from the healthy standard may be the result of very serious disease, or may cause very serious disease : and they will be spoken of hereafter when the disorders of the parts or functions connected with each shall be discussed.

3. Those which are separated from the blood merely to be excreted — as the urine, certain secretions from the bowels, and from the bronchi and skin. Some of these are extremely worthy of study, as indications of disease ; but they require no particular consideration in this part of the course.

Dismissing, therefore, for the present, all further account, as well of the fluids that concur to form the blood, as of the fluids that issue from the blood, let us enquire what morbid changes the blood itself is liable to undergo.

The blood, then, is subject, first, to remarkable variations in its *quantity*, both in respect to the whole system, and in respect to particular organs and tissues.

2. Closely connected with these differences of quantity is the variety which is observable in regard to the proportions between the several constituents of the blood. The changes that occur of this kind are sometimes strikingly evident to our senses. For example, we not unfrequently perceive that the blood drawn from a vein is thinner, manifestly more watery, less rich in fibrin and in colouring matter, than blood of the standard quality.

3. Again, independently of mere alterations in the relative proportions of its constituent parts, the blood is liable to great change in its chemical composition, and, therefore, in its physical quality. This appears to be the case in sea-scurvy, and in the analogous disease called purpura, and it is doubtless so in many other complaints.

Diseases of the alimentary canal, interfering with the process of chylification, must affect the blood : diseases of the organs of respiration, interfering with the arterialization of the blood, will alter it : diseases of other channels of excretion—the bowels, the biliary apparatus, the kidneys, the skin — will (as I have already hinted) indirectly contaminate it : so will various foreign matters, gaining entrance, as they may when in solution or in a gaseous state, through artery, vein, or any membranous structure, such as bladder and intestine : and so, also, there is good reason to believe, will certain states of the nervous system.

But contenting myself with having indicated these latter changes, or sources of change, I shall defer giving a more particular account of any except those that relate to the *quantity* and the *distribution* of the blood.

I say the blood may undergo important alterations in its *quantity*. It may exist in too great abundance throughout the body ; and it may exist in too great abundance in certain parts only of the body. These states have been recognised for ages. Sometimes they are called respectively general and partial *plethora* ; sometimes general and local *congestions* of blood ; people speak also of irregular *determinations* of blood to different organs ; and, of late, the term *hyperæmia*, first invented by M. Andral, in France, has been imported into this country, and much adopted here: all these words and phrases mean, in truth, the same thing ; and their frequent recurrence in medical works, is, of itself, sufficient evidence of the frequency and importance of the conditions which they express.

If we comprehend rightly this subject of plethora or congestion, we shall be prepared to understand some most important morbid states, of which it seems to be in many, if not in all cases, the earliest approach—the initial step. Inflammation, hæmorrhage, dropsy, all acknowledge and imply a previous condition of congestion. "There is probably," says Dr. Alison, " no kind of diseased action of which any part of the living body is susceptible, which is not connected,

sooner or later, with increased afflux of blood towards that part, either as its cause or its effect; and the immediate object of all our most powerful remedies is to act on these irregularities of the circulation."

That the blood *may be* differently distributed in the capillaries at different times, we know by the variable colour of the surface, which depends upon the varying degrees of fulness of the cutaneous blood-vessels. The phenomenon of blushing, the red cheek of anger, the heightened colour of the skin under brisk exercise, are familiar facts illustrative of partial plethora of the capillaries, consistent with health.

There are reasons (which I shall hereafter lay before you), for believing that a similar sudden accumulation of blood, taking place in internal parts, may sensibly disturb their functions; causing transient fits of giddiness, insensibility, and sometimes death itself, when the congestion affects the *cerebral* blood-vessels, and attacks of difficult breathing when the capillaries of the *pulmonary* tissue are concerned; and even *these* attacks, for aught that I know, may end fatally.

It often happens that when certain portions of the surface, as the cheeks, are visibly redder and fuller of blood than usual, or when such symptoms as I have just referred to denote the probability of some internal congestion, other parts of the surface, as in the extremities, are visibly paler: and there are, at the same time, corresponding and palpable differences of temperature.

Perhaps it may not be so obvious that the whole quantity of blood, throughout the body, is sometimes in excess.

That in the adult state, when the growth or increase of the body has been completed, blood may be made in greater abundance, and more rich in the materials of nutrition than the wants of the body require, is not only conceivable, but true. We are able to assign circumstances in which this is likely to happen, and we find that under such circumstances it actually does happen. Full living, and a sedentary life, are causes likely to occasion general plethora — and they do occasion it. The full diet, so long as the digestive powers are perfect, provides more chyle, conducts into the blood a larger quantity of its proper pabulum. The sedentary life precludes that freer circulation of the blood, and that more liberal expenditure of it through the skin, and by means of the other organs of secretion, which would occur under more active habits. Persons thus circumstanced are apt to grow fat; the adipous tissue seeming, in these cases, to form a kind of safety valve for the diversion of the superfluous blood. Such persons have turgid and florid cheeks, red lips, red mucous membranes, and (not uncommonly)

ferretty eyes. Their entire vascular system is preternaturally distended. If you open a vein, you find that they bear a large abstraction of blood without fainting, and are even refreshed by it; and the blood drawn separates into a large and firm mass of coagulum, with but little serum. Keeping to the nomenclature we have already employed, we might say that there is here *hypertrophy* of the blood.

When inflammation arises in the subjects of this general plethora, it runs high, and requires active treatment. But they are not, as you might naturally expect them to be, and as many writers state them to be, peculiarly prone to suffer inflammatory complaints. There is general fulness of the vascular system, but no irregularity, nor any necessary tendency to irregularity, in the distribution of the blood.

You will observe that the relative proportion of the more solid to the more fluid constituents of the blood is increased in these cases of general plethora: the blood is not only more abundant, but it is richer also in fibrin, and in red particles.

The means to be adopted for redressing this unnatural and unsafe condition of the circulation, are those which common sense would suggest. The abstraction of a part of the superfluous blood, a more restricted diet, a larger allowance of active exercise.

It will be worth our while to contrast this state of general plethora with its opposite— that in which the blood is scanty and poor— what Andral calls (though with questionable propriety) *anæmia. Oligæmia* is the cacophonous but more exact name assigned to it by Gendrin; but *poverty of blood* is the ordinary English phrase for it, and the best. This is a state which we can produce at will, by abstracting blood from the body in moderate quantity, but repeatedly, and at short intervals. It occurs, also, frequently, in spontaneous disease, and from various causes; from a privation of the materials destined to replenish the blood; and in cases in which these materials appear to be turned to little account, as in chlorotic girls. We see it in those who habitually and frequently lose a certain quantity of blood, in disease; in persons, for example, who are subject to piles, and who bleed daily from the rectum; still oftener in women who suffer repeated hæmorrhages from the uterus. When the drain has been long continued, these persons become very pale; even those parts which are naturally most red, as the lips and tongue, become almost white; their faces look like wax; and if still you draw blood from a vein, and allow it to coagulate, you will have a small clot floating in an abundance of serum, and that small clot will be of a light rosy colour; showing a great diminution in the proportion of fibrin, and a

still greater deficiency of the red particles. The blood, as they say, is "turned into water." It is a curious pathological fact, that the red particles require more time for their restoration than the other constituents of the blood. And I may mention to you now, what I shall have to repeat, that in conjunction with the obvious curative measures comprised in arresting the habitual loss of the vital fluid, and in affording sufficient nutriment to the system, the preparations of iron, and the respiration of pure air, have signal efficacy in renewing the red particles, and giving back again their native hue of redness to the cheek and lips.

In general plethora every part is preternaturally full of blood, and the blood itself is full of the elements of nutrition. General plethora therefore implies, *in one sense*, local plethora of every organ and tissue. In strictness, however, local plethora is only predicable of a part that contains more than its share of red blood.

Now the converse of this is not true, as it might be expected to be, of the opposite condition. A deficiency in the whole mass of blood contained in, and circulating through the body, does not protect the *parts* of the body from congestion—from having an undue quantity of blood sent to them. Far from it. Local determinations of blood are *very common* in persons in whom the mass of that fluid, and the proportion of its nutritive materials, have been considerably diminished by disease, or by hæmorrhage.

This remarkable tendency, under such circumstances, to an unequal distribution of the blood in the capillaries, admits (I think) of this explanation. A due supply of healthy blood is requisite for the steady and equable performance of the functions of the brain and nerves. When this supply is defective, or uncertain, those functions become disordered and irregular, and, in their turn, influence the various solids, disturb their action, and derange the balance of the circulation. That the capillary blood-vessels may be filled to excess, or completely emptied, by causes operating *through the nervous system*—by moral emotions, for example—we are sure from the phenomena just now adverted to, the blush of shame or anger, the paleness of fear ; and there can be no doubt that *morbid* congestions, which sometimes are separated from those that are consistent with health by very slight shades of difference, are often determined through the agency of the same nervous system. And persons endowed with great sensibility or irritability of the nervous system are very liable to partial or irregular congestions of blood.

But this is not the only way in which local congestion may arise.

We can produce it, upon the surface of the body at least, at pleasure, and that in various ways : by friction, by exposing the part to a high temperature, by certain stimulating applications, mechanical (as a cupping-glass), or chemical (as a mustard poultice) : we produce an injection of the small cutaneous blood-vessels ; there is, evidently, more than the usual quantity of blood attracted to the part, or detained in the part—a degree of redness, which soon subsides if the cause of it be withdrawn in time.

Congestion thus occasioned is not inflammation, but it is the first step towards that complex process ; and for that reason it deserves all your attention. Apply the exciting cause a little longer, or increase, in a slight degree, its intensity, and the phenomena of inflammation begin to manifest themselves.

I said we can produce local congestion, when we please, upon the *surface* of the body : but there can be no doubt that a similar state may be produced by analogous causes, in internal parts. Look at this representation of the stomach of a dog *(one of Dr. Roupell's plates)*. You see one portion of it of a bright red colour, actively and vividly congested. This was the consequence of a dose of alcohol. We may be certain that something of the same kind is the result of every visit to the gin shop.

Local congestion thus produced, or of this kind, is said to be *active*. M. Andral, whose nomenclature has come much into fashion of late years, calls it sthenic, or active hyperæmia. The arteries, perhaps, have more to do with it, in the first instance, than the veins. But it is in the capillary vessels, which are distinct from, and interposed between the minute arteries and veins, that further changes are wrought, when the process advances a stage beyond mere local plethora. What has been observed, by the aid of the microscope, with respect to the blood-vessels, I will endeavour to describe to you.

I take the account I am about to give you chiefly from Kaltenbrunner, a German pathologist, who has recently investigated the subject experimentally, and whose observations are believed to have been most carefully and skilfully conducted, and their results no less faithfully narrated. His observations were made upon the circulation as it appeared in the web of a frog's foot, under a powerful microscope. It would be idle, and something like committing a fraud upon you, were I to lay any stress upon my own knowledge or experience in this matter, for I cannot pretend to any great skill in the use of the microscope, and my opportu-

nities of noticing, by its help, the phæno-
mena of the circulation, have been too few to
render their results of much value. Yet it
may be in some degree satisfactory to you
to know that I am not blindly repeating
the remarks of others, and that what I
have witnessed is perfectly in accordance
with the statements of Kaltenbrunner, and
affords me a strong assurance of his accu-
racy and fidelity. There is another reason,
too, why I consider him the more trust-
worthy — he has no theories to which he
might be disposed to bend or accommodate
his facts.

Before I detail to you his account of the
phænomena of congestion, I may briefly
describe the scene which presents itself when
the web of a frog's foot is looked at through
a good microscope. It is a most beautiful
and wonderful spectacle, and particularly
interesting to those who, like ourselves, are
desirous of gaining some insight into the
healthy and diseased states of the circula-
tion. It is a sight which I hope and believe
you also will have many opportunities of
seeing in this place. You perceive, then,
occupying the circular field of the instrument,
a number of blood-vessels, through which
the blood, with its globules, is in active
motion ; and you see at once that there are
three different kinds of vessels before you.
First you notice the blood shooting with
great velocity along tubes which divide and
subdivide into smaller and smaller branches,
each branch (speaking generally), going off
at an obtuse angle : these are plainly arteries.
Then, in another part of the field of view,
you see the blood moving in the contrary
direction, more slowly, in larger trunks,
which are formed by the continual union
and accession of smaller and tributary
vessels of the same kind, that meet, for the
most part, at acute angles : these you know
to be veins ; and all the intermediate and
surrounding surface in view is occupied with
other vessels or channels, which connect
themselves with the ultimate ramifications of
the arteries on the one hand, and with the pri-
mary radicles of the veins on the other, but
which differ from both arteries and veins in
these particulars – that they interlace and anas-
tomose in all parts, in a very irregular man-
ner, and at all angles, and that they retain
every where the same uniform size ; they
neither collect into larger and larger trunks,
nor separate into smaller and smaller
branches, but are disposed like the threads
forming the meshes of a net, except that the
interstices are irregular in size and shape.
These are the true capillaries, intermediate
between the arteries and the veins, and
perfectly distinct in character from each,
but communicating and continuous with
both.

If now you press upon the animal's leg,

so as to obstruct the circulation a little, the
motion of the blood is retarded, especially
in the capillaries. You see the globules
slowly following one another. These so-
called globules are not spherical, but have
an oblong form ; and you may sometimes
see one of them sticking in a capillary
channel, its long diameter having got at
right angles to the direction of the current :
other globules accumulate behind it, till at
last they all pass on again together.

Now Kaltenbrunner irritates the web by
pricking it, and soon afterwards the follow-
ing appearances present themselves :—There
is an increased afflux of blood to the part,
so that arteries, veins, and capillaries, re-
ceive a column of blood two or three times
as great as usual ; the velocity of the blood
is accelerated ; the distended sides of the
vessels seem to tighten around the stream of
blood which they contain. With this altera-
tion of the circulation, the natural functions
of the part begin to be modified. The
change of the blood from arterial to venous
is interrupted. The globules, passing with
great rapidity through all the vessels, retain
the characters of arterial globules even when
they arrive at the veins ; they present a
bright colour, shew a tendency to stick
together, and often form little clots, which
pass through the capillaries and become
visible in the veins.

One of the natural functions of the web
is the secretion of a kind of lymph ; but
this secretion is now suspended. The
parenchyma itself begins to be slightly
tumid, and assumes a brighter tint than
common.

All these phenomena begin from a cir-
cumscribed spot, of which the circumference
gradually expands as the affection increases ;
and they cease insensibly at that circum-
ference.

This is active congestion.

A certain period always intervenes between
the first action of the irritant cause, and the
commencement of true congestion. This
period, the occurrence of which you will be
good enough to bear in mind, Kaltenbrunner
calls the period of *incubation* ; the period in
which the congestion is *hatching*.

Active congestion, as such, does not con-
tinue long. It either passes on into inflam-
mation, as I shall hereafter explain, or it
begins to decrease. When it has been very
slight, the quantity of blood, and the ra-
pidity of its movement, diminish gradually
from the circumference towards the centre ;
and in this way the congestion insensibly
vanishes.

But in other cases, when it has not been
so slight, the congestion terminates by an
evident crisis, which Kaltenbrunner thus
describes :—The blood, receding from the
circumference of the congested part towards

the centre, gives out, by exhalation, a liquid. The exhalation takes place by fits, and here and there, through the sides of the capillary tubes, and generally on the surface of the organ. The moment of exhalation is very transient ; but it is repeated often, and in different spots, until the congestion has disappeared. It is evidently critical, for the congestion is relieved and extinguished in proportion as the exhalation is repeated.

I shall follow these consequences of active and continued local congestion no further at present ; but merely remind you again that the changes I have last mentioned constitute the earliest appreciable modification of structure leading or belonging to inflammation. What we thus may see (and it is what I myself have had some opportunities of seeing) in the transparent textures of animals, we reasonably infer to take place, under analogous circumstances, in those parts of the body which are internal and opake, and consequently hidden from our view.

I will just observe, also, that as active congestion is the parent of inflammation, so it sometimes causes hæmorrhage, and is relieved by it. But, comparing this form of congestion with another which I am about to mention, the connexion of hæmorrhage with it is, relatively, unfrequent.

One obvious mode of remedying this congestion is the mechanical abstraction of blood from the loaded part. But it is seldom that this measure alone suffices ; and sometimes it would be ultimately hurtful to adopt it. The state of the constitution may be such, that the disposition to local plethora would be increased by the loss of blood. Disordered action and undue susceptibility of the nervous system are apt to be aggravated by bleeding ; and in proportion as the nervous functions are irregularly performed, does the tendency to unequal distribution of blood in the capillary vessels augment : we have daily examples of this in hysterical young women. It is not, therefore, the mere congestion that we have to consider ; we must look deeper, for its cause. Leave a small thorn in the finger—the blood will be collected there in consequence of its irritation—and will continue to collect in spite of depletion. But extract the thorn, and your remedial measure of taking away blood is at once successful. So it is also with internal congestions of blood—of which the exciting and sustaining cause is not always so well known.

Contrasted, in some important particulars, with active congestion such as I have been describing, is that morbid fulness of the capillary vessels which arises when the return of the blood from them towards the heart through the veins, is impeded by some *mechanical* obstacle. With this *mechanical* congestion the veins are exclusively concerned.

Congestion of this kind may be strictly local. It may be confined to a single limb, when the principal venous trunk belonging to that limb is compressed, or otherwise diminished in size ; and when no collateral and compensatory channels for the returning blood have been established. If there be disease of the liver, of such a nature as to prevent a free passage of the blood through that organ, congestion will ensue in all those parts of the capillary system from which the blood is conveyed by the veins that ultimately concur to form the vena portæ. The force of gravity alone is sufficient to produce venous congestion, and consequently congestion of the capillaries, in parts of the body in which, under ordinary circumstances, the circulation through the veins is aided, instead of being opposed by that force. If, for instance, the head be suffered to hang downwards for a certain time, we see the unequivocal signs of such congestion in the tumid condition and the purplish red colour of the lips, cheeks, eyelids, and ears. When an impediment to the free transmission of blood exists in the heart itself, a tendency to stagnation is produced, first in the venæ cavæ, then in the smaller ramifications by which these veins are fed, and at length in the general system of capillary vessels : and thus even general congestion may proceed from a physical cause ; the parts that are the most vascular being also the most readily and the most completely gorged.

There is yet a third form of local congestion, differing, in some respects, both from active and from mechanical congestion. The capillaries become loaded, and the course of the blood in them is languid and sluggish, without any previous increased velocity of the blood in the arteries, and independently of any mechanical obstacle in the veins. To this form of congestion the term *passive* is applied. Andral denominates it passive or asthenic hyperæmia. I will tell you the class of facts from the observation of which the real existence of this passive plethora has been ascertained.

In persons enfeebled by age, or by disease, the lower parts of the legs, the insteps and ankles, and the skin which forms the surface of old scars, are often habitually purplish, or violet coloured. There is congestion of dark blood in those parts. You may, perhaps, be ready to ascribe this to the mere influence of gravity upon the blood, but this cannot be the whole explanation, because the force of gravity is the same with all persons, and at all ages. A horizontal position of the limb will perhaps diminish the livid redness, or may even sometimes entirely remove it. But the depending position ought not to cause it, and would

not cause it, if the blood-vessels were in a healthy condition. Neither can the difference of posture be any source of *irritation* to the congested part. The capillaries themselves appear to have lost, in a great degree, their natural elasticity ; they easily dilate under the pressure of the blood, which, being thus retarded, accumulates in the part. The employment of friction, or some stimulating application, will often remove this congestion.

I say all this is often to be noticed when there has been no cause of irritation operating upon the part, and no preceding state of active congestion. But it is important to mark the very frequent connexion that exists between these contrasted conditions. The one very often succeeds the other : the vessels become dilated under the force of the active hyperæmia, and, the irritation ceasing, they do not at once recover their tone, but remain passively loaded and distended. They are frequently left in the same state upon the subsidence of inflammation.

Take another illustration from what you may any day witness in respect to indolent ulcers. You will find that the large, flabby, and livid granulations which they present, may be made to contract, and to assume a more healthy and florid hue, by local stimulants ; these evidently act by quickening the previously languid circulation, and unloading the congested capillaries.

Observe, again, what not unfrequently happens in regard to the eye ; a little organ, indeed, but one that supplies us with more striking lessons in pathology and therapeutics than any other portion of the body. You know that the conjunctiva and sclerotica, through which, while healthy, colourless fluids alone circulate, are traversed, under various forms of disease, by innumerable vessels bearing red blood. Now it is notorious that, in certain cases, the application of any stimulating substance to the surface of the organ will increase the existing redness, multiply the number of visible vessels, and aggravate the complaint. These are cases of active congestion, dependent upon irritation that is still subsisting. But it is equally well known to practical men that the blood-vessels of the eye are liable to congestion of a very different kind. They are seen to be distended, somewhat tortuous, almost varicose, and the redness has a browner tinge, and is less vivid, than in the former case. In this kind of vascular fulness—or in this *stage* of it, for it sometimes succeeds to active congestion — emollient applications do harm rather than good, while strongly astringent and even irritant substances will often promptly dissipate the vascularity. These, again, are cases illustrative of congestion of the asthenic or pas-

sive character. The strong topical irritants restore the feeble and relaxed vessels to their natural elasticity, stimulate them to contract upon their contents, and to force onwards the red blood, which they cease to admit from the arteries ; and the redness vanishes.

In the production of *active* congestion the arteries appear to be principally concerned : in the production of *mechanical* congestion, the veins : in *passive* congestion, the capillaries—which, strictly, are neither arteries nor veins, but lie between the arteries and the veins—are the vessels chiefly in fault.

If we turn our thoughts from the visible textures of the body to those which are hidden internally, we shall find reason to believe that these also are equally liable to similar conditions of passive congestion. Take those exceedingly vascular organs, the lungs, through which the whole of the blood circulating in the living body has to pass. The lungs, as might be expected, are *very* liable to congestion and engorgement of their capillary vessels. Oft times this is clearly active, and the result of some irritating cause. But it is not always so. Many of you recollect the epidemic disorder called the influenza, which was so prevalent here in the spring of 1831, and again in the early part of 1837. Among the most constant and striking characters of the disease were the symptoms of pulmonary catarrh ; and it was remarkable how long, in some persons, these symptoms persisted. After the pulse had regained its natural frequency of beat, and when all fever had ceased, the patient would continue to breathe with constraint and some labour, to wheeze a little, to cough, and to expectorate mucus. As all febrile disturbance had subsided, and no further benefit seemed to flow from adhering to what is called the antiphlogistic system, it was a reasonable conjecture that this disappointing obstinacy of some of the symptoms might depend upon a lingering but passive congestion of the pulmonary mucous membrane. And the nature of the *juvantia* confirmed the truth of this conjecture. Tonics and stimulants, so far from aggravating the pectoral symptoms, speedily abated or removed them.

You cannot fail, I think, to perceive the important bearing of these distinctions between active and passive congestion upon our notions of disease and our choice of remedies. These distinctions are not to be discovered by the knife of the anatomist. You must take care not to confound a knowledge of pathology, in the proper sense of that word, with a knowledge of morbid anatomy. Pathology comprehends not only the visible changes of structure which accompany disease, and are disclosed by death, but the processes by which those changes

are effected in the living body, and the laws which govern those processes.

There is one important law ascertained in respect to both active and passive congestion—viz. that it is apt to *recur ;* that those parts are most liable to suffer it, or inflammation, which implies it, that have suffered it before. We may often turn our knowledge of this general fact to good account, in what is termed the *prophylaxis* of disease—in devising means for warding off disorders.

I have stated that *active* and *passive* congestion sometimes occur in succession, the latter being a sequela of the former. So, also, it may be said of *passive* and of *mechanical* congestion, that they often exist *together.* If the capillaries of a part or organ be much enfeebled, the mechanical effect of the gravity of the blood may suffice to bring them into a state of congestion. It is thus that Andral explains the occurrence of a gorged condition of the posterior portions of the lungs (evinced by symptoms during life, as well as by inspection of those parts after death), in persons who, having laboured under no previous pulmonary affection, have been confined to a supine position by long-continued disease or debility. This state of the capillaries is called by Lerminier the " engorgement of position ;" and by Laennec, " the pneumonia of the dying." It neither proceeds from irritation, nor has it the essential characters of inflammation ; although it is apt to be considered an evidence of inflammation by the mere morbid anatomist.

Again, as active congestion, when continued or intense, is antecedent and conducive to inflammation ; so is mechanical congestion, when it reaches a certain point, the prolific source of hæmorrhage, and the almost constant precursor and immediate cause of a large class of dropsical effusions.

I spoke a little while ago of general plethora, as a state in which the whole mass of blood circulating in the body is excessive in quantity, and rich in quality—full of fibrin and of colouring matter, thick with globules. But the blood, as a mass, may be in excessive quantity, yet poor in its materials, serous, deficient in globules, and fibrin, and colour ; and in this condition of the blood also, as we shall hereafter see, dropsies are apt to arise.

We have now, therefore, laid the foundation for the better understanding of those three great classes of disease—*Inflammations, Hæmorrhages,* and *Dropsies.*

There is no region or organ of the body exempt from these diseased conditions and their consequences ; and of each of them some general account must be given, before we come to consider the special diseases incident to the several parts and organs.

But previously to entering upon this general account of inflammation, of hæmorrhage, and of dropsy, we have still some other preliminary matters of importance to discuss. The causes and modes of death. The causes of disease. A sketch of the nature, classification, and import of symptoms.

Our enquiries hitherto have related to the manner in which the physical conditions of the various parts of the body are capable of being altered, and their functions disturbed or suspended, in disease. But how it happens that some of these alterations of structure, or interruptions of function, are incompatible with the further continuance of life, and put a stop to the working of the whole machine, is an enquiry of no less interest, though of a somewhat different kind.

EXPERIMENTS FOR 1839-40.

IN consequence of having been appointed to conduct the experiments on the motions and sounds of the heart for the current year, without being associated with any colleagues, I thought it desirable to avail myself of the assistance of such of my friends, including the other members of last year's committee, as could attend, and I accordingly requested the co-operation of a considerable number of gentlemen known to the public. Of those several were enabled to attend on numerous occasions, and one of them, Dr. Boyd, resident physician of the St. Marylebone Infirmary, on every occasion, so that every observation and experiment has been witnessed by one, or in most instances several, of the following gentlemen, to several of whom I am indebted for very important assistance :—

Professor C. J. B. Williams ; George Gulliver, Esq., F.R.S. ; John George Perry, Esq. ; Dr. G. Hamilton Roe ; Dr. George Burrows ; Charles Cochrane, Esq. ; Dr. Rutherford ; Francis Kiernan, Esq., F.R.S. ; J. Siddell, Esq. ; T. K. Pritchard, Esq. ; Francis Samwell, Esq. ; Dr. Edwin Harrison ; R. A. Stafford, Esq. ; Benjamin Phillips, Esq., F.R.S. ; Dr. Robert Boyd ; and other gentlemen, private friends of the Reporter, and the last four named gentlemen his

colleagues in the staff of the St. Marylebone Infirmary.

The experiments were performed in a convenient locality immediately adjoining the St. Marylebone Infirmary, and principally on donkey colts of a few months old. In the latter part of the series other animals, and especially dogs, were used, partly for economy and in order that the limited pecuniary resources at my command might not be prematurely exhausted; and partly because certain experiments contemplated were expected to prove more easily and decisively practicable on the larger heart of the ass, than on any smaller, such as that of the dog; and that in any event it was desirable to extend the range of observation as far as practicable over the animal scale.

The mode of preparation was in all cases nearly the same. In almost every case sensibility was withdrawn as completely as was practicable, by one method or other. In donkeys, I availed myself of the stupefying property of the woorara poison, for a packet of which I had been indebted since 1838 to Sir B. C. Brodie. The woorara was brought into operation by injecting a couple of grains of it, partly dissolved, partly suspended in water, into the external jugular vein, as practised by Mr. Mayo in an experiment of Dr. Hope's, and the injection was usually followed in a very few minutes, by complete insensibility. In smaller animals prussic acid was used in several instances, and in a few the subject was stunned by a blow on the head. Artificial breathing was used in every warm-blooded subject, by means of a bellows and long flexible tube kept loose in the trachea; the chest was opened, nearly as directed by Galen (de admin. anat.), and as practised by former committees, and 5 or 6 ribs, at least, were separated from the sternum, and broken near the articulation, and bent back over the vertebræ. In every case, whether during the preparation or subsequent observation, all convenient means were used, as advised by Galen, to prevent or lessen hæmorrhage, in order to avoid, as much as possible, the anomalous modes of action attending extreme vascular depletion, and to prolong the opportunities of observation and experiment.

The observations about to be detailed consist partly of experiments in continuation of the enquiries of former committees, and partly of experiments conceived and performed with a view to decide several points in dispute amongst physiologists of authority, which were not investigated by those committees, and which seemed to me yet unsettled, and at the same time important enough to call for direct experimental investigation. The following are the principal of those undecided questions.

1. With respect to the rhythm of the motions of the auricles and ventricles, several living distinguished physiological writers appear to hold, that those cavities act in strict alternation with each other, and not continuously or in immediate succession, the auricles being first in systole and diastole, and the ventricular actions being last before the Rest, as described by Steno, Harvey, Lancisi, Haller, Senac, &c.; and by Hope, Williams, Carlile, Pennock, and Moore, and other distinguished living experimentalists.

2. With respect to the share in the circulation due to the auricular systole, it has been declared to be active, and of much importance, by Harvey, Senac, and others; while several living writers of great weight, adhering apparently to the views of Galen, Vesalius, &c., seem disposed to refuse to the auricles any very influential or positively important share in the cardiac operations; for examples I may cite Dr. Elliotson, Prof. Bouillaud, Dr. Hope, Sir B. C. Brodie, &c.

3. With respect to the shape and dimensions of the ventricles in systole, it was held by Galen, Vesalius, Harvey, &c., that the heart is shortened in diastole, and lengthened in systole; but the observations of Steno, Lower, Lancisi, Haller, and others, gave currency to opposite views. Of late, however, the ancient opinion has been revived; for example by Professor Burdach and Professor Bouillaud, as I understand their observations, and by Drs. Pennock and Moore, the latest experimentalists on the subject that I know of, except my friends and myself.

4. With respect to the præcordial impulse, the great majority of physiologists, adhering unqualifiedly to the ancient opinion, advocated by Hippocrates and Galen amongst the Greeks, and by Vesalius, Harvey, Lancisi, Senac, Haller, Hunter, &c., ascribe the cardiac pulsation to a blow or stroke (in the popular meaning of those words) given by the heart's apex in systole to the ribs; and refer the apparent inaction in the heart, between its pulsations, to the retreat of the organ during its diastole inwards, and away from the walls of the chest. But in opposition to this view may be cited the experiments of several recent observers, and the arguments of Mr. Carlile, of Dr. Hope (in his last edition), of Mr. Bryan, of Dr. Billing, &c. &c.

5. With respect to the diastole of the heart, it was held by Galen and Vesalius to include a strong force of *suction*, by which principally the venous current was forwarded and the auricles were emptied; and this power of inhalation or suction has been adopted by numerous living authorities; *e. g.* Professor Bouillaud, Dr. Hope, and Dr. Copland; and has even been extended to the auricular diastole, *e. g.* by Professor Alison and Dr. Elliotson. The exertion,

systole, giving place to an opposite state of the parts, or to a state of convexity and even of protrusion in the central parts.

Section 2.—The finger and thumb were then applied to opposite sides of the ventricles, and were felt to be abruptly pushed outwards in systole, and to approach each other in diastole, if acted on even slightly by the flexor muscles, and with marked depression of the parietes in diastole, during which no sense of active resistance was experienced.

Section 3.—A wooden stethoscope was then placed on the ventricles, and kept erect by means of a roll of paper large enough to give the instrument full freedom of motion, and the uniform result was, that, wheresoever placed on the ventricles, the stethescope was heaved up with a jerk at each systole, (to the height of half an inch near the fundus), and subsided at once in diastole, causing in the parietes a deep depression, which was wholly removed by the systole, and succeeded by an opposite shape of the surface.

Section 4.—To the eye and hand the fundus appeared to become round, hard, and elevated and to give impulse somewhat sooner than the apex, as if the systole was developed earlier about the fundus than at the free extremity of the heart.

Section 5.—To the fingers, during the systole of the ventricles, a feeling was communicated, as of an undulation in a compressed fluid, very distinct, and directed from fundus to apex, and resembling sensations familiar to clinical physicians in ascites, hydrocele, &c. when properly percussed.

Section 6.—On touching the arteries close to the heart, a feeling as of efflux and reflux was very distinct, especially in the aorta; the former coinciding with the systole of the ventricles; the latter with the diastole. At the same moment with the outward current in the arteries, or during the ventricular systole, a peculiar jerking upwards of the periphery of the auriventricular orifices, and a similar eccentric movement was observed over the arterial openings during the reflux current or undulation in the vessels, or during ventricular diastole.

Section 7.—The sinuses of the auricles were found by the touch to contract vigorously, before the ventricles considerably, and even before the shrinking, &c., or systole of the appendices.

Section 8.—Small triangular pieces of white card were made to adhere to the fundus and apex cordis respectively, and observation was made through a roll of paper sufficiently large to take in at a convenient distance both extremities of the organ, and held so that each white object rested on a distinct limb of the tube's mouth, and every change of distance between the points dotted

white was readily detectible; and the uniform result was, that the apex approached the base in systole, and receded again in diastole, and the mean range of oscillation seemed about one-third of an inch.

Section 9.—While the heart still acted, but with much diminished force, a cut was made in the right auricle, and a copious flow of blood obtained, having slight jets in the auricular systole, and immediately before the ventricular hardening, elevation, &c. but being continuous during diastole.

Section 10.—The ventricles appeared not to differ in size on careful examination post-mortem cordis.

[To be continued.]

ON PERICARDITIS.

By JAMES DOUGLAS, A.M.

Lecturer on Anatomy, &c. &c.*

[*For the London Medical Gazette.*]

IN the following essay I propose, 1st, briefly to sketch the history of acute pericarditis; 2ndly, to examine its pathology; 3dly, to inquire into its diagnosis; 4thly, to speak of its treatment; 5thly, to illustrate the preceding divisions by some cases, several of which have occurred under my own observation; and lastly, to notice the consequences which result from it when chronic, or not immediately fatal.

1. Pericarditis is the inflammation of the serous membrane which lines the fibrous sac of the pericardium, and covers the heart and origins of the great vessels. It may be either acute or chronic. Such is the definition given by Laennec.

Pericarditis comes on, like other inflammatory attacks, generally with a feverish paroxysm, coldness and shivering, followed by heat, and afterwards by a moist state of the skin, which ordinarily persists throughout the progress of the case. Sometimes the pulse is frequent, full, strong, and regular, accompanied by heat and moisture of the skin; sometimes, on the other hand, it is small, unequal, irregular, and very quick, while the skin is hot and dry. Sometimes, in connection with this latter set of symptoms, the extremities become cold, and are covered with a cold sweat, as in cases of fainting.

* Read before the Glasgow Medical Society, 17th March, 1840.

There exists sometimes a dyspnœa, or insufferable feeling of oppression; the patient cannot lie still, but is in a constant state of jactitation, as if unable to get breath; the face is pale, the features are contracted, and wear a most anxious expression; sometimes there are twitchings or spasms of the muscles of the face, occasionally putting on the appearance which has been called the sardonic grin. When the dyspnœa is carried to the last degree, the movements exhibit all the marks of forced respiration, the nostrils being dilated, the inspirations short, frequent, and constrained, as in pleurisy; sometimes delirium, sometimes insomnolence, sometimes convulsions, more or less general, are superadded. When the disease continues for some days before terminating in death, the face becomes pale and livid, and the limbs become anasarcous, as we see in most cases of obstructed circulation, from whatever cause.

Pain is not a constant attendant on pericarditis. When it does exist, it generally comes in sharp darting paroxysms, striking through the region of the heart to the back; but very often the only uneasiness complained of is a sense of weight at the heart, and sometimes, particularly in cases of rheumatism, the pericarditis is altogether latent.

Death from pericarditis takes place either from syncope, brought on by the obstacle to the heart's action, produced by the liquid effusion, or adhesions, or it is caused by the wearing out or exhaustion of nervous energy, met with in all cases of long-continued acute inflammation.

If resolution take place, a gradual amelioration of the symptoms occurs; but as the cure must almost necessarily be by adhesion of the inflamed surfaces, a degree of impediment to the heart's action generally remains, which is very apt, in the long run, to give rise to hypertrophy.

The causes of pericarditis are, exposure to cold, direct violence, such as fracture of the sternum or ribs of the left side, and what is still more common, the extension or metastasis of rheumatic inflammation. The similarity of structure in the joints and pericardium is the cause of this extension or metastasis. In both cases there is a fibrous membrane, which may or

may not be inflamed; and in both cases there is a secreting sac, inflamed in all cases of pericarditis, and in all cases of acute rheumatism. The synovial membranes are well known to be very similar in structure to the serous ones, and sympathize strongly with them; as, for instance, we have sometimes synovitis following upon peritonitis, or accompanying pleuritis, and both caused frequently by inflammation of the lining membrane of the veins, which is itself a serous membrane. Bouillaud considers that one half of the subjects of acute rheumatism have pericarditis. When the pericarditis comes on, and the rheumatism continues, we would say it is certainly an extension of the disease; and when the rheumatism ceases as the pericarditis commences, many call it a metastasis. But is there a real metastasis? Does the inflammation leave the joint *to* attack the pericardium? or does it not leave the joint *because* it *has* attacked the pericardium? This is still a disputed question.

Pericarditis may follow traumatic inflammation of a joint also, as will be shewn by a case in the sequel. It has also been known to follow scarlet fever, and the suppression of cutaneous eruptions. According to the statement of Bouillaud, persons between the ages of 10 and 30 are the most liable to its attacks.

2. Acute inflammation of the pericardium, like that of all similar membranes, is characterised by redness of its surface, by effusion of coagulable lymph, and by the pouring out of a serous, sero-sanguineous, or sero-purulent fluid.

The redness is almost always slight in the acute disease, and seldom pervades the whole of the inflamed portion. It is not formed by distinct vascular ramifications, but is mostly in dots, as is seen also in acute inflammations of the other serous, and in synovial membranes, when inspected in the first stage. Scarcely ever does it happen that we see the pericardium in this stage of inflammation, for the effusion of lymph comes on very early, and then the vascular mottling is discoverable only by peeling off the false membranes, or where we see it in the interstices between them. The pericardium is rarely if ever thickened; what has been described as thickening has generally

been a deposit of lymph on its surface, which has become organised, and in a manner incorporated with it.

Very soon after the increased vascularity which constitutes inflammation has occurred, the overcharged vessels pour out their pale straw-coloured fibrine, which speedily becomes coagulated on the surface of the membrane, obscuring the redness, and taking on various irregular forms.   Generally fibrine and serum are secreted together, and the former coagulates while the latter remains fluid.   The coagulum of fibrine varies much in thickness, but from the twelfth to the fourth of an inch may be considered as the medium. It does not in general present a smooth or even surface, as the false membrane in pleurisy does, but is rough, and has a multitude of irregular prominences. These are sometimes like the surface of a honeycomb, or like the second stomach of a calf ; sometimes, though rarely, in detached lumps ; sometimes like a pustular eruption, whence it has been absurdly stated that small-pox has been seen in the pericardium ; occasionally it hangs in shreds like tow, and in other cases is marked with undulating lines, like the sand on the sea shore.   Generally it has the appearance produced by separating two slabs covered with lard, presenting numerous prominences and depressions, caused, of course, by the friction of the surfaces covered with the soft exudation. When the lymph becomes old, it occasionally puts on a darker colour, and becomes even of a brownish red. In such cases, where not adherent, there is usually secreted a bloody serum.

If no fluid be effused, or that which has been effused becomes absorbed, then the parietal and cardiac layers come into contact, and adhere.   By and by, the medium of adhesion has vessels shooting into it, and becomes organised ; it now puts on the appearance of cellular membrane, its thickness in a great measure disappears, and if an opportunity of inspection occur some years after, the layers are found completely blended into one.

In most cases, an effusion of serum accompanies that of coagulable lymph. The surfaces are thus prevented from adhering, and become separated, and, if inspected in this stage, will be found smooth.   A preparation on the table exhibits this ; it was taken from a

child.   The pericardium contained a large quantity of muddy serum, by which the surfaces were widely separated ; they are seen covered with lymph, and have, evidently, never been adherent.   The drawing which I took of this case, when recent, exhibits the lymph in patches, with the vascularity of the membrane appearing in the intervals between them.

The serum is sometimes transparent, of a faint greenish yellow, or fawn colour ;   but more generally it is opaque and milky, or containing shreds or flakes of imperfectly concrete lymph floating in it.   Dr. Hope says this mixture of lymph is rarely seen ; but in the cases which have occurred to me, it has been almost always present. Its quantity varies from a couple of ounces to a pint, or even more. Sometimes the effusion is hæmorrhagic, such as is occasionally seen in pleuritis, and then, of course, its colour is a more or less deep red.

The quantity of the effusion may become so great as materially to impede the action of the heart, and produce fatal syncope ; but generally it, after a time, becomes absorbed, and then the false membranes adhere, and the cavity of the pericardium becomes obliterated.   Sometimes the false membranes become organised, and a continual balanced process of effusion and absorption goes on, the fluid gradually changing its character, so as to become sero-purulent, and the patient dies of irritation.   It is said that true pus is scarcely ever found in the pericardium, probably because the intense irritation carries off the patient before the suppurative process becomes fairly established.

Sometimes we find that lymph has been effused from many points of the serous surfaces, producing adhesions, and that while these are still soft, serum is poured out from those parts of the surfaces which are non-adherent, and by its accumulation the adhesions become elongated.

In some cases the inflammation of the investing membrane extends to the muscular substance of the heart, producing what is properly called carditis. Of this affection it is not at present my intention to speak ; suffice it to say, that in such cases the colour of the muscular substance will be much deepened for a part of its thickness ex-

teriorly, if the case be recent; and will be paler than natural, if so chronic that lymph have been effused, or it have become firmer than in the healthy state.   More frequently the lining membrane of the heart also becomes inflamed, in virtue of that sympathy by which all the serous membranes are so linked together.   The membrane assumes a red instead of a yellow colour, and sometimes lymph is effused, putting on the form of vegetations, or, at least, rendering the membrane opaque, which is naturally transparent.   I had several specimens of this opacity of the endocardium, but the appearance is lost by the opacity given to the healthy membrane by the spirits.

It does not appear that the pericardium is subject to either ulceration or gangrene.

3. The diagnosis of pericarditis is the point where practitioners, till of late years, were most at fault.   When discovered, it is as amenable to treatment as other membranous inflammations; but when latent, it was of course allowed to destroy the patient, without ever being put in check.   The general symptoms which have been mentioned above, in the history of the disease, are plainly those of all thoracic inflammations; and though from some of them, in some cases, pericarditis might be guessed at, none of them could be depended on with certainty.   M. Collin, in 1823, in his Manual on the Exploration of the Chest, pointed out the "leather creak," as he called it, as a diagnostic mark of pericarditis.   Laennec had thought this sign valueless, for in his treatise it is not even mentioned. For ten years this sign lay dormant, if I may so speak, and if we except a notice in Broussais's Pathological Commentaries, which attracted no notice, it was only in 1833 that the attention of the profession was called to it, by Dr. Stokes, of Dublin, who has the merit of almost re-discovering it, at least of pointing out its almost universal application.   I will now give a short abstract of the remarks which he has appended to his cases, in the Dublin Journal for September, 1833.

The direct diagnosis of pericarditis is formed on the observation of certain phenomena produced by the morbid condition of the serous surface of the pericardium, which are twofold; we have phenomena perceptible by the hand, and phenomena perceptible by the ear.

In the natural state of serous membranes, the gliding of one surface over another meets with no opposition, and is not accompanied by any sound; but when, from the effusion of lymph, these surfaces become roughened, we have sounds produced by the friction, and vibrations communicated to the surface, often perceptible to the hand.   The motion of ascent and descent of the lung is inaudible in the healthy smooth state of the pleura, but a friction-sound is generated in dry pleurisy; and in the same manner the effusion of lymph on the internal surface of the pericardium is rendered obvious to the senses both of touch and hearing.

The friction-sound is *always double*, accompanying both the systole and diastole of the ventricles; but varies considerably in its character.   In some cases there is a rasping-sound, like that heard in the worst cases of ossification of the valves; in some it has the creaking of new leather; in others it is soft, and similar to the bellows-murmur, but in all it is *double*, and *quite superficial*.   The rubbing sound varies in character on different days, and is much modified by the effects of treatment.   After a free application of leeches, the sounds are often speedily and singularly changed, passing from a very loud rasping to a soft bellows-murmur, with complete disappearance of the feeling of friction.   Further, it is an important element in the stethoscopic diagnosis, that the friction-sound is audible only over the heart, and is lost on moving the instrument one or two inches away from it.   The extent over which the sound is heard varies according to the extent of the pericardium which is inflamed; sometimes it is heard only over a small portion of the heart's surface; more commonly over the whole; and sometimes, on different days, it may be distinctly traced extending.

If adhesions of the inflamed surfaces takes place, of course the sound disappears, when the surfaces no longer move on one another.   But the friction-sounds may disappear from another cause, viz. the effusion of fluid separating the rough surfaces.   In this case, the region of the heart will be more dull than natural on percussion; and if

the treatment have the effect of caus-
ing absorption of the fluid, then the
friction-sound will re-appear on the
rough surfaces coming again into con-
contact. When, however, the effusion
is moderate, the friction-sound does
not disappear over the whole heart,
but only towards the apex, the rough
surfaces remaining in contact towards
the base of the heart.

After the surfaces have completely
adhered, and the disease has arrived at
the only cure of which it is susceptible,
a bellows-murmur often continues,
quite different from the previous fric-
tion-sound. Sometimes this depends
on inflammation of the membrane
lining the heart, or endocarditis; but
more generally, 1 believe, on the ob-
struction to the heart's freedom of
motion produced by the adhesions.
This obstruction seems to excite greater
efforts, which generally terminate in
hypertrophy.

I will now finish what I have to say
of the diagnosis, by transcribing Dr.
Stokes's conclusions, or the general
results of his researches.

" 1. That in cases of pericarditis
with effusion of lymph, the rubbing of
the two roughened surfaces causes sounds
perceptible to the ear, and communi-
cable to the hand, by which the dis-
ease may be readily recognised, even
when all other symptoms are absent.

2. That the more rough the serous
membrane is, the more distinct will
these signs will be.

3. That those sounds accompany
the two sounds of the heart, in almost
all cases.

4. That they are audible, generally,
only over the region of the heart.

5. That they present themselves with
various modifications of character, but
often resemble the sounds of extreme
valvular disease.

6. That they are most distinct when
the region of the heart continues with
its natural sound on percussion; but
that the existence of fluid does not ne-
cessarily imply their complete subsi-
dence.

7. That they may re-appear after the
absorption of fluids from the bag of
the pericardium, or from the new super-
vention of inflammation.

8. That the sounds may continue
when the sense of rubbing is no longer
perceptible by the hand.

9. That they are singularly and

rapidly modified by direct antiphlo-
gistic treatment.

10. That by observing the progress and
mutations of these signs, we can trace
the progress of organization, or of obli-
teration of the pericardiac cavity,
judge of the effects of treatment, and
accurately ascertain the exact state of
the pericardium.

11. That hence, auscultation is of
direct use in pericarditis, and that the
diagnosis no longer rests on *negative*
signs."

CASES AND OBSERVATIONS

ILLUSTRATIVE OF THE

MERCURIAL TREATMENT OF SOME FORMS OF INCIPIENT PHTHISIS PULMONALIS.

By WILLIAM MUNK, M.D.,

Physician to the Tower Hamlets Dispensary.

[For the Medical Gazette.]

THE idea of employing mercury as a
curative agent in the early stage of
some forms of phthisis pulmonalis, oc-
curred, we are informed, about the
same time, and without any mutual
communication, to three of the most
distinguished physicians of the Irish
capital. These were, Sir Henry Marsh,
Dr. Graves, and Dr. William Stokes.
The two latter of these gentlemen have
laid before the public some of their
earlier experience on this interesting
subject. The first communication
which appeared was from Dr. Graves,
and is contained in his published clini-
cal lectures, whilst the experience of
Dr. Stokes will be found detailed in his
excellent treatise on the Diagnosis and
Treatment of Diseases of the Chest.
The results of this practice in the hands
of Sir Henry Marsh are not, so far as
we know, yet before the profession.
Dr. Corrigan, more recently, in a very
interesting lecture, has pointed out the
class of cases, and the stage, in which
this mode of treatment is admissible.

Before entering further on the sub-
ject, it may be well to give a sketch of
the circumstances which have led to
this mode of treatment, and, in so doing,
I shall avail myself of the words of
Dr. Graves, offering no apology for the

length of the quotation, the interest attaching to the subject seeming to me a sufficient reason for so long an extract.   After speaking of the effects of mercury in some inflammatory affections of the joints, and in some forms of inflammation of mucous membranes, the Queen's Professor goes on to say, " This puts me in mind of a plan I have adopted within the last year, in the treatment of certain diseases of the lung, and on which I shall make a few observations, as it has not been spoken of by those who treat of the cure of pulmonary affections.   I must here in justice confess that the idea of this plan of treatment is not solely mine, but was founded on an analogy derived from the researches and experiments of Dr. O'Beirne, on scrofulous inflammation of the joints.   An extensive experience and deep reflection first led Dr. O'Beirne to think that the acute stage of scrofulous inflammation of the hip and knee joints might be made amenable to active and energetic treatment ; in other words, that inflammatory affections of the joints, which terminate in some of the worst and most fatal forms of disease, namely, morbus coxæ and white swelling, might be checked *in limine,* and before the stage of hopeless ulceration was established.   He, therefore, proceeded boldly and at once to try whether the disease might not be arrested in the commencement by rapid mercurialization.   Observe, gentlemen, the idea was completely new ; it had never occurred to any other person, and was diametrically opposed to the theories of the day.   The prevailing opinion on this subject was, that mercury was inadmissible, and could only produce mischief in persons of scrofulous diathesis.   Every one said, do not give mercury in such a case, it exasperates scrofula ; it even brings on scrofula in many instances where there had been no appearance of it previously.   You can do no good with it, but may do infinite mischief.   Dr. O'Beirne, however, knew the difference between the proper and improper exhibition of mercury—between mercurializing the patient at once and fully, and then stopping, and the pernicious custom of giving long and irregular courses of mercury.   He tried the remedy, and succeeded, and the surgeons of Europe have justly appreciated the value and importance of

this discovery.   About two or three months before Dr. O'Beirne made his discovery public, I had translated for the Dublin Medical Journal a paper from a German author on the use of corrosive sublimate baths in the treatment of white swelling, and Dr. O'Beirne states that the publication of this paper gave him courage at the time in pursuing a plan of treatment so much at variance with the opinions of the day.   I published this paper, however, at the time, merely as a curiosity ; it was a novelty in practice, of which I had no experience, and could not offer any explanation.   This was reserved for Dr. O'Beirne.   He has shown in his memoir on the subject, that if you give mercury so as to affect the system rapidly, you will frequently succeed in curing the disease, particularly in the commencement.   From this I was led by analogy to apply the same principle of treatment to incipient scrofulous inflammation of the lung, and I think I have often succeeded in checking at once this most formidable of human maladies*."

The results of this practice, as hitherto published, are as follow.   Dr. Graves states in general terms that he could mention many cases which have been treated successfully on this plan, and then proceeds to particularize three in which its action was manifestly curative.   It failed, however, in two cases in which he had confidently expected benefit.   Dr. Stokes mentions six cases in which he made trial of the mercurial treatment.   In two of these a permanent recovery ensued.   In two, temporary, though well-marked relief, was experienced.   In one instance it was useless, and in another the medicine manifestly disagreed.   Dr. Corrigan narrates but one case, yet this is decidedly in favour of the treatment, for the patient speedily recovered.   Exclusive, then, of the experience of Sir Henry Marsh, who is reported by Dr. Graves to have found this mode of treatment beneficial,   there are for reference twelve cases.   In six of these a cure resulted, in two considerable benefit, in three it was useless, and in one the medicine disagreed.

Small as is this experience when numerically considered, and insufficient as to the decision of a point so com-

---

* LONDON MEDICAL GAZETTE, vol. xx. p. 339.

I

pletely at variance with the doctrines of the schools, it nevertheless appears to us that the evidence above adduced, coming as it does from persons so well qualified to form an opinion on the subject, has attracted far less of attention than its intrinsic importance legitimately demands : out of twelve cases of a disease so uniformly fatal as phthisis, there have, under a new and peculiar mode of treatment, been six cures. This will probably to many persons be a startling assertion ; and I have therefore, before making it, been careful to state distinctly from what sources the information has been derived.

On investigating the pathological condition to which the observations of the authors above quoted refer, we shall find that conclusions as to its nature and seat must be based almost wholly on the general symptoms and physical signs ; post-mortem examinations serving our purpose but little, inasmuch as few cases prove fatal at this period of its course. These circumstances combined make necessary a large amount of observations before any certain conclusions can be obtained ; and they tend, in no inconsiderable degree, to render doubtful to many members of the profession the opinions maintained by those who have given attention to the subject, whilst they no less cause the treatment pursued, and the success which is stated to have resulted therefrom, to be regarded with some degree of suspicion. This is, perhaps, but an illustration of that salutary caution which, within certain limits, should mark our conduct in reference to new views and novel modes of practice hence derived, more especially when, as in cases like the present, many of the arguments are deduced from negative rather than from positive facts.

The form of disease now under consideration very commonly attacks individuals in tolerable or even apparently perfect health, although, if their previous state be minutely investigated, it will, I believe, in such instances, be found that there exist more or fewer indications of deterioration of habit, in the shape of scrofulous cachexia—whether that be of hereditary origin, or has been acquired by error in some of the non-naturals. Its commencement is, in the majority of instances, sudden

and well marked ; its immediate exciting cause clearly ascertainable, being in general owing to the application of some of the common causes of inflammation ; or it originates, as do other local inflammatory affections, during the course of fever, of the exanthemata, influenza, &c. The phenomena attending it are those which point to a lesion of the bronchial mucous membrane, pulmonary parenchyma, or, as is most frequently the case, the two combined ; that lesion being evidently inflammatory in its character, as evidenced by pyrexia, and by the existence of the physical signs and general symptoms of bronchitis and pneumonia.

The disease, in its most frequent form, commences after the manner of a common catarrh. The patient having been exposed to moisture, or a low temperature, often the two combined, experiences a sensation of chilliness, which may augment to actual rigors. These are attended by languor, and indisposition to bodily or mental exertion, pains about the back, and aching of the limbs ; to which succeed heat of skin, increased frequency and strength of pulse, thirst, and a more or less unnatural appearance of the tongue. The respiratory organs evidence disorder ; the voice becomes somewhat altered ; irritation is perceived about the larynx, giving rise to frequent dry and irritative cough. As the case proceeds soreness is experienced beneath the sternum, a sense of tightness across the thorax ; more frequent cough, which either then, or within a short period, is accompanied by expectoration, at first of a watery, saline, and irritating character, but which soon mellows down into a clear, tasteless, viscid fluid, scanty in quantity, and expelled with some difficulty. In other cases the expectoration presents characters different from those just mentioned ; it is more abundant, brought up with ease, and, in lieu of being clear and tasteless, is opaque, sweetish, and pus-like. These symptoms individually or collectively may be more or less severe ; they do not, in the majority of instances, arrive at such a height as to induce the individual to place himself at this period under medical care. The indisposition is looked upon as a common cold, perhaps more than ordinarily severe. Yet it is subjected at this time to domestic remedies alone.

Should the practitioner, however, have an opportunity of examining a case at this period, he will find modified bronchitic râles over more or fewer parts of the chest, existing perhaps only, or at any rate greatly preponderating, in the apex of one or both lungs. After continuing for an uncertain period these symptoms undergo modification; some may altogether disappear; but in general a diminution of severity is alone experienced. The patient from hence flatters himself that he is improving; but the speedy addition to the category of symptoms of no mean import, dispel the illusion, excite fears as to the indisposition, and cause him then to seek professional advice. There is emaciation and loss of strength; the phenomena of common pyrexia merge into or are changed for those of hectic, among the symptoms of which rapidity of pulse and morning perspirations will be found the most marked. There is severe and harassing cough, with or without a viscid purulent expectoration, considerable hurry of respiration, shooting pains about the shoulders, disturbed and sleepless nights. The stethoscopic signs at this period consist of a minute and clear mucous rhonchus, more properly, perhaps, designated by the term muco- or sub-crepitant, and existing only in the superior portions of the lung. In other cases there is heard at this part of the chest a modification of the normal respiratory sound, which, when once distinguished, can never afterwards be mistaken, but the description of which in words, as of most other sensations, is a task of difficulty. The respiratory murmur is here somewhat modified, scarcely if at all diminished in intensity, yet giving the sensation of being moister, as though the bronchial tubes were lubricated with more fluid than in their healthy state; not, however, as it would seem, in sufficient quantity to produce the subcrepitant or mucous rhonchi. In these instances we may occasionally, by very careful and prolonged examinations, detect at long intervals, especially on a deep inspiration, a solitary and minute mucous bubble. Here we generally find that expectoration is exceedingly slight, or altogether wanting; whilst in the cases presenting the subcrepitant or mucous rhonchi, expectoration does exist, although rarely to any great extent. Little or no infor-

mation can be obtained from percussion during the earlier periods of the disease, the chest then sounding perfectly well. As the case, however, advances, more or less dulness is perceived; and when this occurs, the active auscultatory signs undergo a corresponding modification. At first there is an increase in duration and intensity of the expiratory sound, giving to the whole respiration a sensation of greater roughness: this increasing, passes onwards into well-marked bronchial respiration, coincident with which there is bronchophony and bronchial cough. It were useless to trace these cases further: tubercular matter has now been deposited in considerable quantity, the case is one of confirmed phthisis, and the period for the employment of mercury has passed.

Such will be found the commencement and course of many of the cases of phthisis which are amenable to mercury in their earlier stages. Sometimes, however, the disease takes its origin in a severe and universal bronchitis, which at once calls for medical interference and for active treatment. There is here great feverishness, considerable embarrassment of respiration, and intense bronchial rattles over the whole chest. General and local bloodletting, with tartar emetic, seem to be here clearly indicated; and although it be found in the sequel that these measures are not so well borne as the symptoms would have led us to expect, still from their employment the patient derives considerable relief. The activity of the disease is broken, the fever is diminished, the respiratory oppression relieved, and the bronchial râles lessened both in intensity and in extent. The stethoscope indicates, however, that the morbid action still lingers within the lung, and that the superior lobes are the parts now alone affected. The remedies which had proved effectual in the removal of inflammation from the other parts are powerless over these; and their continuance serves but to debilitate the patient, and to hasten on the disease to an incurable stage. The lesion here existing may, however, be removed, but its removal can be accomplished in no other way than by the employment of mercury, so as to produce its specific effects upon the constitution. If the mineral be not had recourse to, the

case goes on from bad to worse; percussion and auscultation evidence the deposition of tubercular matter within the lung, and incurable consumption is thus induced.

Another and not unfrequent mode in which this disease originates remains now to be noticed. Allusion is here made to those cases the commencement of which is distinctly traceable to some general disorder of the whole system, as, for instance, essential fever, the exanthemata, influenza, &c. In the course of all these there is a great liability to congestions, determinations of blood, and inflammation. The bronchial mucous membrane and pulmonary parenchyma become frequently affected in this manner, the supervention of such morbid state being, in some instances, proclaimed by symptoms so well marked, that the lesion from whence they originate cannot be overlooked. In far the greater number of instances, however, the local disease is to a greater or less degree latent, the marks of general disturbance being so numerous and severe as to cast into shade or obscure the more feeble manifestations of low morbid action in the lung. The former class of cases being at once recognised, are promptly met by appropriate treatment, the local disease is subdued, and the disastrous consequences to which it tends thus averted. In the latter instance, however, the local affection often goes unrecognised, and no measures are adopted for its removal; or, if it be discovered, its severity is frequently underrated, and means employed which prove inadequate to the end proposed. In either case the phenomena are similar to those before enumerated; they indicate a low inflammatory action of one or more tissues of the lung, existing only in the top of the organ, or, if more extensively spread, greatly preponderating in these parts. Should this condition continue, the patient presents a like succession of symptoms to those we have described above as occurring when phthisis supervenes upon catarrh, modified however, in some measure, by the nature and usual course of the disease in whose progress they have arisen. There is an analogous mitigation and modification of the local and general symptoms, together with the addition of other phenomena dependent on the disordered state of

the lung, and the disturbances in other organs to which its sympathetic relations give rise. The patient experiences what appears to be a long, tedious, and unsatisfactory convalescence. After a time he retrogrades considerably, and the symptoms of pulmonary disease come prominently forward. The efforts of the practitioner to relieve the condition of general disorder are set at nought by the local disease, which proves an insurmountable weight to the resiliency of the constitution. Emaciation progresses, the symptoms of hectic appear, and after a time the physical signs testify the deposit of tubercle in the lung.

It may probably be urged by some that the term phthisis cannot with propriety attach to the lesion of the respiratory organs above described, inasmuch as the active and passive auscultatory signs differ widely from those commonly laid down by writers as indicative of this disease, and point only to low bronchitis or pneumonia. The justice of this objection we are forced to admit, if the term phthisis be employed in a limited sense, and as expressive only of those cases in which tuberculous matter has already been deposited within the lung. But regarding the subject in a practical point of view, we come to an opposite conclusion: for abundant experience testifies that the transition from the state above described to that of confirmed phthisis is gradual and progressive; that in point of fact the condition now under consideration is neither more or less than that which determines scrofulous deposition to the lung, whilst it is, at the same time, the very action by which this deposit is effected.

In the three cases above described, phthisis, from neglected though mild bronchitis—as the sequel of severe bronchial inflammation inefficiently treated, or as ensuing upon bronchial or parenchymatous inflammation occurring during the course of other and general disease—there is found only a sibilant, clear mucous, crepitant, or muco-crepitant rhonchus; these persist for a long period, and are, during the early stage, unaccompanied by other signs. The sonorous rhonchus is rarely heard; the mucous exists in a diminutive form, approximating in character to the crepitant; the expectoration but rarely undergoes the same rapid suc-

cession of changes observed in pure ordinary bronchitis, but remains clear, tenacious, spumous, observing more the habitudes of peripneumonic or of bronchopneumonic disease. This combination of symptoms points therefore more to the minute bronchial tubes as the seat of disease, than to either the larger tubes or the parenchyma. It presents much resemblance to that form of disease termed capillary bronchitis, but is attended by less expectoration than is usually found in this disease, when occurring in its more usual site, the lower portions of the lung.

Now if it be asked, says Dr. Stokes[*], what gives these signs of bronchitis their value as diagnostics of incipient tubercle, the answer is, that it is not by their mere characters (for these do not differ from ordinary bronchitis), but it is from their situation[†], localization, and combination with comparative dulness of sound, that they derive their value. The same phenomena scattered over, or even existing intensely throughout the lung, but being equable, and unaccompanied by dulness, would not only have no value in the diagnosis of phthisis, but would render the existence of tubercle improbable. Simple bronchitis is seldom circumscribed, while that of the consumptive is commonly so: the latter begins in the upper portion of the lung, remains obstinately fixed in the air tubes, gradually spreads downwards, and while in its first stages in the lower lobe is combined with tuberculous ulceration in the upper: it may be intense in the upper lobe while the lower is altogether free, or engage the whole of one lung while the other is scarcely affected. These are not the characters of ordinary bronchitis.

A new aspect has been given to the pathology of tubercular disease by the investigations of Sir James Clark[*], Dr. Carswell[†], and the late Dr. T. J. Todd[†], who have proved that, for its production, a previous morbid condition of the system must exist : in other words, that a necessary element in the causation of scrofula is a certain cachexia or abnormal state of the fluids of the body. In what this consists has been most clearly shown by Dr. Carswell, whilst the circumstances leading thereto have no less satisfactorily been elucidated by Sir James Clark and Dr. Todd. From the united labours of these gentlemen have resulted the important pathological law, that *tuberculous matter exists as a morbid constituent of the blood, is eliminated from it by a process analogous to, if not identical with, secretion, and is thus deposited, in a visible form, in different organs or parts.*

The contamination of the blood exists in some cases for a long period, and proceeds to a great extent before the deposition of tubercle commences. It seems not improbable that in such instances the sanguineous fluid becomes so thoroughly saturated (if the phrase be allowable) that an attempt at relief is then commenced, and nature sets about the work by eliminating the morbid product in conjunction with the secretions. Dr. Carswell is of opinion that the surfaces of mucous and serous tissues are those upon which tubercular matter is chiefly deposited; that as regards relative frequency the former very far exceeds the latter; for here, he says, " as into the great emunctory of the system, it appears to be separated from the blood, and becomes visible to us under a variety of forms." Dr. Carswell is at issue with most pathologists as to its deposition in the molecular structure of organs. In no one instance has he witnessed it so situated. Our own observations tend to an opposite conclusion, although we doubt not that the most frequent sites of tubercle are those pointed out by Dr. Carswell. We believe, with most pathologists, that tubercular matter has

---

* Treatise on the Diagnosis and Treatment of Diseases of the Chest, p. 392.

† Louis, says Dr. Cowan, has *invariably* found that the sibilant, mucous, and submucous rales resulting from simple catarrh, originate in the *lower part of the chest*, while bronchitis complicated with pulmonary tubercles is always situated in the *upper lobes*. Simple bronchitis usually attacks *both* sides of the chest, while rhonchus from tubercles is *at first* almost constantly confined to the upper lobe of one side. Of the immense importance of this law there can only be one opinion, and, in many instances, attention to the seat of bronchitis would dissipate much doubt and anxiety, and early indicate the real nature of an affection which, without the knowledge of this fact, would frequently be confounded with simple catarrh, and thus frustrate the hopes both of the patient and practitioner.

no peculiar site; that it *may*, under certain circumstances, appear in any organ or part of the body, making its appearance there by a lesion of nutrition, whereby such matter is secreted in place of, or in union with, those molecules of the blood, which, appropriated to the organ itself, become an integral portion of its structure, and thus repair the losses it is ever undergoing.

This deposition is frequently a silent process; it commences and proceeds to a certain point, unaccompanied by any known pathological state, or, if phenomena of disorder do occur, they are to be regarded as effects or coincidences rather than as causes. It will probably be found that this relation obtains only in those cases where scrofulous cachexia, and the contamination of the blood, which is its essence, has proceeded to a considerable degree, and where the local deposit is the result of the overcharged condition of the blood, rendering relief by the elimination of some portion of the morbid constituent indispensable.

In other, and, perhaps, the majority of instances, tubercle is deposited long ere the cachectic state has arrived at the degree above supposed. In these such an event is determined by irritation or inflammation, under the influence of which there is a larger afflux of blood to the part, and coincident with it an increase and modification of secretion. In lieu of the results of common inflammation, as occurring in a healthy subject, there is here deposited tubercle, or coagulable lymph variously modified, the modification consisting . in the approximation of that product more or less closely in character to tubercle. The analogy which exists between these two morbid products, and the mode in which one may pass into or give origin to the other, has been clearly shewn by Dr. C. J. B. Williams. Its further consideration here would extend these remarks to an inconvenient length; I shall, therefore, content myself with referring those who may wish to enter fully on the subject to the third vol. of the Library of Medicine, p. 166, et seq.

[To be continued.]

REPORTS OF CASES,

By H. M. HUGHES, M.D.

Assistant Physician to Guy's Hospital, and Physician to the Surrey Dispensary.

[*For the Medical Gazette.*]

Bronchitis.—The number of persons so severely affected with this disease as to be unable to attend at the dispensary, and therefore visited by me at their own houses, during the year between March 16th, 1839, and 1840, was twenty-six, a number larger than that attached to any other complaint, with the exception of phthisis. The comparatively large number of those affections, which are primarily induced, or the progress of which is accelerated by cold and wet, as rheumatism, bronchitis, and phthisis, concurs with the small amount of the cases of fever in marking that year as one particularly free from those grave epidemic typhoid diseases which are usually common in the district to which these reports are confined, as well as in those adjoining it.

Of the twenty-six cases referred to, eight were examples of simple, acute, or subacute inflammation of the bronchial membrane, and in the remaining eighteen this inflammation existed, generally in the chronic form, in combination with emphysema of the lungs, and more or less dilatation of the right side of the heart, either temporary or permanent. Of the cases of simple bronchitis it is sufficient to observe that they were induced by common causes, and treated successfully on common principles; the chief or most important remedies employed for their cure being blisters, antimonials, and saline aperients. There appears to be no disease, with the exception of chronic rheumatism, which is so much affected by atmospheric changes, and which, after temporary relief, is so likely to be reproduced in all its former intensity by a cold and damp air, as chronic bronchitis accompanied with pulmonary emphysema. On this account it was that the disease was unusually troublesome and obstinate at the end of the last and commencement of the present year, when wet and cold weather continued for many successive weeks.

The ages of the patients varied from three to seventy years; their complexion,

temperament, and occupations, also varied considerably. It is not, I think, generally known that young children are liable to, and not very unfrequently affected with emphysema of the lungs, and that from the cradle they are subject to many or most of the inconveniences that occasionally accompany it. Mothers sometimes assert that their children were *born* with a "shortness of breath," and generally add that they are themselves, or that the father, or some other near relative of the particular patient, has been long "troubled with asthma." That pulmonary emphysema may not be congenital, or even hereditary, I am not prepared to deny, but I am not aware of the existence of any pathological observations which can be considered conclusive evidence of the fact; and I am certain that almost all the cases that have fallen under my own notice have upon inquiry been traceable to a severe attack of hooping-cough, or bronchitis following measles. I must, at the same time, admit that I have seen a few instances of this disease, particularly in rickety subjects, in which after a considerable investigation I have not been able to ascertain the prior existence of any such complaint. The plan of treatment that I have found most beneficial in these cases, of whatever age, is the application of counter-irritants to the chest, and the use of hydragogue cathartics, and a combination of alkalies and expectorants. In children the ammonia liniment, with or without a little tincture of cantharides, according to the susceptibility of the patient, or the effect produced, applied to the chest night and morning, and a mixture containing Liq. Potass., Tr. Scillæ, Vin. Ipecac., and Syr. Papaver. taken three or four times a day, with an occasional aperient if requisite, I have almost always found effectual in removing the temporary complaint, if the weather has been favourable to such a result. In the adult, repeated blisters, the compound camboge pill, or jalap, as a purgative, and mixtures of the same kind as those administered to children, or others containing ammonia, decoction of senega, squills, and compound tincture of camphor, varied according to the condition of the individual patient, have often afforded very marked and speedy relief. Several also, for whom the inhalation of the smoke of stramonium has been pre-

scribed, have been extremely energetic in announcing the benefit they have derived from its employment. It has generally been ordered to be smoked just before retiring to rest, and the stated effect has been a decrease of bronchial secretion, less cough, and a comparatively quiet and comfortable night. But till the weather has become mild and dry, all remedies that I have hitherto tried have been generally inefficient for the removal of even the temporary complaint. The pulmonary emphysema has of course remained, and as I have considered it to be the most important of the two complaints, I have placed the patients thus affected, who have resigned their dispensary letters as "cured," among those simply "relieved."

The list of twenty-six cases formerly published contained three dead, seven cured, twelve relieved, and four remaining under treatment. Of these last one has since died. The four cases in which death occurred were the following :—

1. A man, aged 26, by occupation a lamplighter, who from childhood had been subject to the inconveniences resulting from emphysema, frequently increased by severe attacks of bronchitis. While suffering from one of these attacks he imprudently exposed himself in the exercise of his calling to the cold weather in March 1839, and thereby materially aggravated his complaint. When first visited he appeared dying from suffocation; the dyspnœa was extreme; the face was tumid, and of leaden hue; the tongue purple, but loaded with thick moist fur; the pulse very feeble; and the extremities cool. The chest was universally very resonant on percussion, but the bronchial tubes were loaded in every part with thick viscid purulent mucus, which he expectorated with great difficulty. An emetic, a mustard poultice, afterwards a blister, with a mixture containing ammonia and squills, failed to relieve him, and he died exhausted and suffocated in three days.

2. A poor woman, aged 49, by occupation a cutter of orange chips, subject to emphysema from childhood, and liable in damp cold weather to catarrh, with profuse secretion from the bronchial membrane, had been more than once relieved by the employment of blisters and stimulating expectorants, but had renewed her complaint by going out

for her work in consequence of the in-
dolence of her strong and idle husband.
She was not worse than she had been
before, was pursuing the same plan of
treatment which had previously relieved
her, and was upon the point of sending
to the dispensary for some more medi-
cine, when, as I was afterwards inform-
ed, she suddenly expired.

3. A man, aged 56, who had for a
long time been subject to bronchitis
and dyspnœa, and who, in addition to
the ailments of those previously noticed,
had symptoms of disease of the mitral
valve, with ascites and great œdema of
the feet and legs. He varied consi-
derably in the amount of his suffering;
on some occasions being comparatively
free from complaint, and on others
affected with violent dyspnœa; but
never being entirely free from serous
effusion. A variety of diuretics, seda-
tives, and expectorants, which it is
needless to particularize, were em-
ployed; and, till within a few days of
his death, with very considerable effect.
At this time he began to sink rapidly,
and expired very suddenly in a fit a
few minutes after I had left him, ex-
ceedingly ill, but without any appear-
ance of immediate dissolution. Neither
of the preceding cases were examined
after death, and as they presented
nothing very remarkable I have not
thought it desirable to detail them at
length. In the fourth I obtained per-
mission to examine the body, and as
the condition of the lungs, though pro-
bably not very uncommon, was in-
teresting in reference both to pathology
and to diagnosis, I may perhaps, with-
out tediousness, relate it somewhat
more fully.

4. A man, aged 36, of light com-
plexion, with reddish hair and whis-
kers, the son of healthy parents then
alive, became my patient at the Surrey
Dispensary, October 22nd, 1839. He
had been subject to cough in both
winter and summer for thirty years,
which originally succeeded to a violent
attack of measles. He had been occa-
sionally confined to his bed, however,
only during the last three years. He
was by trade a carpenter, and his
habits were regular, industrious, and
temperate, and he was the father of
four healthy children. After exposure
to wet and cold the day before I saw
him, he was affected with increased
cough and dyspnœa, and pain of the

left side : was seen by the apothecary
of the institution, and ordered to apply
ten leeches, and afterwards warm poul-
tices, to the affected side, and to take
Liq. Am. Acet.ʒss., Vin. Antim. Tart.ʒss.,
Vin. Colch. ♏x. Aq. ʒj. every four
hours. When I saw him on the 23d,
the pain of the side had been relieved,
but not quite removed, by the leeches ;
the face was purplish, the dyspnœa
considerable, the cough frequent, and
the expectoration abundant, thick,
yellow, and muco-purulent ; the skin
was moist, the tongue loaded and moist,
the bowels confined, the pulse rather
frequent, soft, and weak, decubitus was
difficult, and the extremities of the
fingers were particularly large and
rounded ("clavate"), a condition sup-
posed by Dr. Bright usually to coexist
with long continued purulent or muco-
purulent expectoration. The chest was
very resonant on percussion, especially
at the upper part, with the exception
of the precordial region, the natural
dulness of which was somewhat in-
creased in extent, though lessened in
its intensity. In every part of the
chest loud bronchial rattles were heard,
which in the inferior portion of the
lung resembled the gurgling of nu-
merous small cavities, and which, in
the superior portion, were accompanied
with the prolonged expiration usually
attending pulmonary emphysema. The
impulse of the heart was feeble, the
sounds soft, and the rhythm natural.
Ordered

By these, and similar remedies, he was
so much relieved as to be able to go
out in three or four days. Without
permission, and contrary to advice and
strict injunctions, he resumed his em-
ployment out of doors in very wet and
cold weather. The next day, as was
expected, he was again confined to his
bed. The disease returned with con-
siderably increased violence, and not-
withstanding the use of emetics, sina-
pisms, blisters, and expectorants, he
expired November 14th.

Inspection by Mr. Nettlefold and
myself fifteen hours after death :—

The body was not emaciated, nor
were the limbs œdematous. The *Head*

was not examined. *Chest.*— On the removal of the sternum the lungs did not collapse as usual, and almost entirely concealed the heart, the right passing over to the left side of the mediastinum. Some old adhesions united the inferior portion of the right lung to the costal and phrenic pleura ; while at the superior part the lung was free from adhesion, and exceedingly emphysematous. Some circumscribed lobular portions were quite white and dry, and felt like parchment, or like a portion of emphysematous lung which had been exposed to the air for preservation. Many of the cells were dilated to the size of millet-grains, and the whole afforded a doughy inelastic sensation to the finger when pressed. The separate lobules collapsed upon being incised. The bronchial tubes were nearly filled with purulent mucus, but the lining membrane was not much injected. The lower lobe on the right side was solid from congestion and œdema (arising from his position in the last few days of the patient's life), and broke down easily by pressure of the finger. All the bronchial tubes were much enlarged; scarcely any diminution was perceptible in their calibre after the second subdivision, till they terminated in what, upon superficial examination, appeared to be culs de sac. The mucous membrane at this part was not thickened, but of a deep purple crimson hue, from congestion or imbibition. The upper lobe of the left side was emphysematous like that of the right, and the lower very œdematous, but became moderately crepitant after the removal by pressure of the contained serum. On a transverse section, numerous small cavities, containing much purulent matter, were exposed; they varied in size from that of a tare to a small bean, and resembled, on slight inspection, small tubercular cavities. By tracing them, however, they proved to be immensely dilated bronchial tubes, with the membrane entire and thin, but dark coloured from injection. They decreased but little in size till they terminated in a blind extremity. The pericardium was healthy. The heart was dilated and hypertrophied, particularly on the right side : its valves were free from disease. *Abdomen.*—The liver was large and turgid with blood, and both externally and upon section presented the nutmeg

appearance so common in cases of diseased heart. The kidney and other organs, though congested, were sound. No tubercles were discovered in any part of the body.

The death of three of the patients whose cases have been referred to above, and particularly that of the last mentioned, was pretty clearly attributable to exposure to a cold and wet atmosphere, while suffering from an attack of chronic bronchitis of not greater severity than was common to them. From this is sufficiently apparent the importance of confining such patients to a warm and dry apartment. Moist air probably acts mechanically as well as vitally in such cases. It not only operates injuriously by relaxing the mucous membrane of the tubes, and increasing its secretion, but, in consequence of its decreased specific gravity, by expanding the air in the already dilated cells, and thereby inducing increased obstruction to the circulation through the lungs, causing a smaller proportion of oxygen to come in contact with the blood. The man Rowe by the treatment at first adopted regained in a few days his ordinary condition. He went out in a drizzling rain to inspect a church then building in the Borough, of the works of which he was superintendent, and a fatal relapse of his disease was the direct consequence. My experience in the use of small doses of sulphate of zinc, administered as an astringent in such cases, is certainly limited ; but in the few cases in which I have ordered it I have not observed the beneficial effects which have been said to result from its exhibition. This patient took it for some time without the slightest apparent advantage.

The exact resemblance of the gurgling present in the lower part of the lungs of the man Rowe, to that accompanying small tubercular cavities with copious secretion, might possibly have led to an error in diagnosis, had not the history, the general symptoms, and some other physical signs, pointed out the extreme probability of that condition which was actually discovered after death. It was not probable that the gurgling arose from phthisical cavities, as it was confined to the lower lobes of the lungs, while simple bronchitic rattles, accompanied with evident emphysema, alone existed in the upper.

The long-continued cough, and the absence of emaciation, rendered the presence of phthisis improbable. But the cavities might possibly have resulted from the softening of the unorganizable product of a low form of pneumonia, which is more frequent in the lower, while phthisis is, in a great majority of cases, in the first instance confined to the upper lobe of the lung. The presence of that condition was, however, rendered highly improbable by the want of evidence of any previous severe inflammatory affection, and by the tolerable health generally enjoyed by the patient, notwithstanding the temporary inconvenience occasionally resulting from his local complaint, and more especially by the absence of the other physical signs of that disease; as dulness on percussion, increased resonance of the voice, and tactile vibration of the parietes of the chest on talking and coughing.

It has been observed by justly celebrated writers on the diseases of the chest, that the difficulty of diagnosis between chronic tubercular cavities and dilatation of the bronchial tubes, is increased, by the latter, like the former, being generally confined to the upper lobes of the lung. This opinion is, in some measure, confirmed by some of the cases related by Andral, Louis, and others; but, notwithstanding the high authority by which it is supported, I may, perhaps, be allowed to express a doubt of its general accuracy. That it sometimes occurs I am well assured; that it is not universal, the case above related, in which the dilatation of the *tubes was entirely confined to the lower lobes*, abundantly proves. From personal observation I am disposed to believe that this bronchial dilatation is ordinarily as general throughout the lung as the bronchitic affection by which it is induced. If, indeed, the opinion of Louis, derived from numbers, that bronchitis principally and primarily affects the inferior lobes, is correct, it would appear at least probable that the dilatation of tubes would also more commonly exist in them than in other parts. But on this subject, as on some others, individual experience compels me to doubt the correctness of his deductions, however highly I may estimate the accuracy of his observation.

CASE OF A

KNOT ON THE UMBILICAL CORD
DESTRUCTIVE OF THE

LIFE OF THE CHILD BEFORE PARTURITION;
WITH REMARKS.

To the Editor of the Medical Gazette.

Sir,

Mrs. D. A., of short stature and 28 years of age, in her third pregnancy, went beneath a bed to fetch a pair of her husband's shoes. On hearing some one coming up stairs, she suddenly backed out from under the bed, rising to the standing posture with a movement of considerable expedition and effort. This was immediately followed by an unusual movement in the abdomen, and with most tumultuous motions of the fœtus, which lasted in a severe and painful degree for a short time. I was sent for to ascertain the nature, and if possible relieve sensations so painful. I found that the fœtal movements had ceased, and directed rest, absolute quiet, and an anodyne to allay the pain of abdomen, as well as to soothe her distress of mind for the loss of her child, which she declared to be dead. This was on Wednesday the 17th of November. Next day her breasts were flaccid and diminished in size; there had been no movement of the child, formerly very lively; and I may add, that she never experienced any movement afterwards. On the afternoon of the 20th of the same month she sent for me. I found her in labour: in three hours from the commencement of uterine action she was delivered of a still-born female, to all appearance come to its full time, or very nearly so. There was one turn of the umbilical cord round the neck of the child. There was nothing particular as to the quantity of liquor amnii, nor was there any remarkable hæmorrhage. As it was dusk, I did not distinctly see the state of the fœtus, and the first intimation of its condition was my finding the cuticle raised by fluid under it into irregular bullæ, and separating by the friction with spirits, which I had recourse to immediately on its expulsion. During labour I observed that the bones of the head overlapped each other considerably more than ordinary. On running my fingers along the cord, I felt a hard firm knot on it, the placenta being still attached. The

natural expulsive powers soon brought it away. On more minute examination I found on the funis umbilicalis, near its middle, a very firm hard drawn and distinct single knot ; so firmly was it drawn, that the parts involved in the knot were reduced to half the thickness of the rest of the cord, when unloosed, and permanently retained this diminished size. The parts so compressed were pale and exsanguineous. From the knot to the fœtus there were spiral turns of the injected arteries of a very dark purple colour, and they became more injected and distended with blood the nearer they came to the abdomen of the child. The vein had less blood in it than the arteries. The arteries of the thorax and abdomen of the child contained more blood than the veins, which were almost empty. The cord, from its placental attachment to the knot, was less injected; indeed it had almost no blood in it, and was of an indistinct blue or neutral tint. The placenta was of natural size, but very exsanguineous, and of a lighter colour than usual. The mother did well, and has since given birth to a healthy living child. Her previous pregnancies and labours were natural.

REMARKS. — From the silence of many English obstetrical writers respecting the existence of knots on the funis umbilicalis, and the occurrence of accidents of the kind just narrated, I was at first led to think that they did not frequently happen. I do not recollect any notice of this particular in the writings of Denman, Burns, and other standard elementary works, and most of the writers who do notice the existence of the knots either deny that they are ever drawn so tight as to destroy life before parturition, or seem to be very doubtful of the possibility of it. I found, however, on a little research, that knots do often exist on the umbilical cord, and I have scarcely ever met a practitioner of much and lengthened opportunity of observation who has not one or more instances of such knots to relate. At the discussion educed by a recital of the above case to the Glasgow Medical Society, in Dec. 1838, Mr. Lyon stated that he had met with a loose knot on the cord of a child born alive and healthy at its full time. Dr. Pagan said that he had witnessed another, the same in kind and in issue. Dr. James Wilson, a very

experienced accoucheur, stated, if I recollect aright, that he had seen several such instances, but none of a tight and fatal knot. Mauriceau (in his Traité des Maladies des Femmes grasses, &c. Observ. 133) narrates a case where an extremely firm knot (véritable nœud extrêmement serré) was found on the cord : the child was born alive ; which shows, he contends, that the tightening of the knot could only have taken place during the passage of the child. He further adds, that from that time till 1694 he had attended seven other women, whose children were all living, who had a like knot, which he thinks arose from the extreme length of the cord. Five of the children were males, three were females. (Vide Obs. 567 of same work.)

Smellie, however, in his treatise on the Theory and Practice of Midwifery, Chap. iii. Sect. i, mentions amongst the causes of the child's death and consequent miscarriage, the formation of a knot. He describes this accident in the following terms. " If the navel-string be long, and the quantity of surrounding waters great, the fœtus while young may in swimming form a noose of the funis, through which, if the head only passes, circumvolution will happen round the neck or body ; but should the whole fœtus pass or thread the noose, a knot will be formed on the navel-string, which if tightly drawn will absolutely obstruct the circulation."— p. 118. In his second volume he gives three cases in which there were knots on the cord. In only one of these could death of the fœtus be properly ascribed to the condition of the cord in question ; that is the first one, which he records as follows. " In the year 1744, my attendance was bespoke to a woman who imagined herself in labour about the end of the eighth month. This, however, was no other than a colicky pain proceeding from costiveness, of which she was relieved by a clyster. In a fortnight after this visit I was called, and found the membranes had broken. The waters were of a brownish colour, and mortified smell. The labour was lingering, and the child when delivered of a livid hue ; the scarf-skin was easily stripped off, the abdomen tumefied, the funis swelled and livid, about ten hands' breadth long, with a tight-drawn knot on the middle.

Smellie's second case presents us with an instance of a child born alive and healthy, though there was a knot on the cord. He does not tell us the kind of knot, but says, as we should have expected, that it was loose; whereas in the first and fatal one the knot is as tight drawn as in the case I relate, which it also resembled in having the knot in the middle of the cord. In Smellie's third case there was a loose knot on the cord, but the child probably died from the lingering labour, during which " the head was squeezed to a great length, and the brain too long compressed in a narrow pelvis." (Vol. ii. p. 272.) Baudelocque mentions that such knots are very often found on the cord without causing the death of the child, or even affecting its development. He adduces an instance of a well-formed child, weighing seven pounds, born with a triple knot on its umbilical cord: in the representation or sketch which he gives the knots are not drawn tightly. (L'Art des Accouchemens, vol. i.) Dr. Blundell, in his lectures, used to relate a case, on the authority of Mr. Rogers, one of his pupils, that occurred at New York, in which there were three knots on the funis; and yet notwithstanding these knots injection could be thrown from one end of the cord to the other without difficulty. (Castle's Princip. and Pract. of Obstet. p. 108, 1st. Ed.) Dr. Ashwell, also, in his Practical Treatise on Parturition, mentions having " counted five distinct knots, but there was no diminution in the size or vital powers of the child." It is much to be regretted that authors do not inform us as to the kind of knot.

It is difficult, I apprehend, to say when and how these knots are formed; at what period of fœtal existence they are made. Certain it is that some have been formed very easily on the funis; whilst others were probably formed when expulsion of the child was taking place. Dr. Wm. Hunter suggests that the cord in such cases is arranged, at the time of parturition, in the form of a loop or coil at and within the margin of the os uteri, and that the head of the fœtus passes through this loop as it makes its exit from this aperture, carrying the umbilical end of the cord along with it, so as to form the knot at the very moment the body passes into the world. This, it is highly probable,

is the process by which one form of the accident in question may be produced, and in all likelihood the most frequent; but surely it is inadequate to explain the instances in which there are three or more knots; nor does it explain, what I apprehend has taken place in the case narrated, and in others of like nature, viz. the death of the fœtus before any expulsive efforts of the uterus. In noticing this last opinion, Baudelocque says it " cannot have proceeded from observation. Eight or ten or more instances of infants born in vigour at the moment of their birth, although they had a knot on the cord, appear sufficient to invalidate such an opinion." (Vol. i. p. 253.) This, to say the least of it, is not the most logical of arguments; nor does Gardien, who entertains the same notion respecting the impossibility of this tightening of the cord producing the death of the fœtus before delivery, adduce any thing more forcible in the way of argument or observation, though his language be positive enough. " Quelsque soient le nombre et la nature des nœuds qui existent dans le cordon, ils ne peuvent jamais se serrer au point de faire perir l'enfant. (Traité complete d'Accouch. t. ii. p. 172.) And again, in the article Cordon Umbilical, in the Dict. Sc. Méd. he says, " Il est donc impossible, puisque le cordon est beaucoup plus long, que la matrice n'a d'etendue que lorsque le fœtus se porte d'une paroi à l'autre de l'utérus, les nœuds puisent se serrer de manière à intercepter la circulation." No process of reasoning, I apprehend, can settle this interesting and curious point; an appeal to observation and fact alone can establish it; and, however high our speculative notions may rise against it, one clear and unequivocal instance, as I submit the one I record to be, demands a belief in the possibility of the accident in question—a matter of some importance, as bearing on points submitted to the medical jurisconsult. I would, then, employ the words of Seneca, and prefixed by Gardien as the motto to his Traité—" Multum restat ad hoc operis multumque restabit, nec ulli nato post mille secula praecludetur occasio aliquid adjiciendi." (Epist. lib. i. Ep. 64.) Nor is the case I now record a singular one; Smellie's is similar; and we find Levret (L'Art des Accouchemens, p. 144, Paris, 1761) and some before him, very

confidently asserting it as their belief that the fœtus was occasionally destroyed before labour by a perfect and tight-drawn knot on the funis, and that a degree of tightness, short of entirely obstructing the transmission of blood by the cord to the child, impeded its development, and stinted its growth. In my case the cord was somewhat shorter than ordinary; it was perhaps made still shorter by the turn round the neck existing before labour began; there was a sudden suspension and permanent extinction of the movements of the child, previously remarkably lively, attended with circumstances (viz. the sudden violent exertion and succussion of the body of the mother) calculated to tighten a knot previously existing, and followed in a moment by phenomena, even violent convulsive movements, which would undoubtedly happen on, and prove characteristic of, the accident under consideration, viz. tightening of a knot on the cord. That the fœtus had been destroyed some time before birth is abundantly evident by the marks of incipient putrefaction which it presented, and that the knot was the cause of its destruction is shewn by as clear demonstration as such a subject will admit of. I am inclined to think that the knot, though not tightened, must have existed before the tumultuous movement of the fœtus, which suddenly and finally ceased because its bulk at this period would not permit a change of position to such an extent as to have formed a new knot, or to have cast it through a noose or loop previously existing. The way, then, most satisfactory to me, of accounting for the accident, and its occurrence at the time specified, is, that a knot, not tightly drawn, must have previously existed, and that the cord being short, and perhaps rendered more so by the turn round the neck, the sudden and energetic movement of the mother effected such a change of position of the child as tightened the knot, to the stoppage of the circulation in the cord and the extinction of its own vitality. I have ventured to think that in its last tumultuous or convulsive movements one or other of the extremities of the fœtus may have got a turn of the cord round it, so as to cause, or assist at least, in the tightening of the knot. The force with which the cord was tied was very remarkable, as the deep indentation on it, at the part involved in the knot, clearly showed. When the knot was undone this indentation continued. I have repeatedly since that time put a similar knot on a cord, and drawn it as tight as I could, but as soon as the knot was undone the indentation entirely disappeared, the knotted part appearing like the rest of the cord. In this respect a knot put on a cord after delivery differs from one put on before it—a fact worthy of remark. Petit, as quoted by Burton (in his Essay on Midwifery, London, 1751,) relates a case where the navel-string of a human fœtus was shewn, which had a knot in its middle, " and the marks of the part that formed the knot could be observed, which proves that the knot had been made long before the woman's delivery." Petit does not mention whether the child was alive or dead at birth, so the case affords little instruction on the nature of the accident under notice, but it verifies my observation, of the marks remaining under the circumstances stated above. Ruysch, in his Observ. Anat. Chirurg. Observ. xi, narrates an instance, accompanied with a delineation, in which the fœtus was destroyed by a very singular modification of knot, or rather twisting, of the funis umbilicalis. He thinks it likely that the accident was caused by the fœtus twisting the cord, in the manner we see daily done, with a bit of string, in order to double it; that is, by twisting the two cords in opposite directions, or only one end of it, the other being fixed; then doubling it, and laying its two portions in close contact, they instantly twine into one cord.

In conclusion it appears, 1st, that knots may exist on the cord without any injury whatever to the fœtus.

2dly. It cannot be doubted that a certain amount of tightness of one of these knots, short of entirely obstructing the circulation in the funis, will affect the development of the child; and,

3dly. The case related, as well as Smellie's case, the experience of Levret and others, clearly shew, that a knot may form on the umbilical cord, and be drawn so tight as to destroy the fœtus, before any uterine action for its expulsion be begun.—I am, sir,

Your obedient servant,

ALEX. J. HANNAY, M.D.

Anderson's University, Oct. 1, 1840.

IODINE TO CHILBLAINS.

To the Editor of the Medical Gazette.

Sir,

In looking over some numbers of the GAZETTE, I find a letter under the head of "Treatment of Chilblains by Iodine," Feb. 29, 1840 ; and as the weather approaches when many will be glad to hear of a remedy for such troublesome visitors, I feel pleasure in bearing my humble testimony *somewhat* to iodine as a cure for chilblains; but I cannot agree altogether with your correspondent, who would have it that, in every instance, it cures. Here I must differ with him ; for though I have found the good effects of it when *first* applied, in every case, I must say that when those individuals had a return of the chilblains the same winter, its application proved ineffectual ; but I must also remark, that it prevents a return for a much longer period than any any other application I know of, and consequently I would give it the preference : besides this, it has the good effect of relieving the pain and itching after the first or second application. Perhaps the manner I ordered it could be improved on, so as to make it beneficial if the person was attacked a second time the same winter. Should any of your correspondents suggest an improvement, I shall be happy to adopt it and give it a fair trial. The form in which I used it was as follows :—

R Tinct. Iodinii, ʒiij. ; Liniment. Saponis Co. ʒv. M. Sæpe applicandum.

I used the soap liniment, because it makes the application more soothing and emollient. I never could apply it when the chilblains had cracked ; but if applied when the parts are red and swollen, it becomes a powerful repellent. I never had occasion to order chamois leather, the liniment proving effectual without any covering.

Your insertion of the above, if worth a corner in your valuable journal, will much oblige, sir,

Your obedient servant,
J. FITZPATRICK, M.R.C.S.

October 5, 1840.

P.S.—I first used it in the winter of 1835.

ON THE

ACTIONS OE THE OBLIQUE MUSCLES OF THE EYE.

BY CHARLES RADCLYFFE HALL.

(For the Medical Gazette.)

Few physiological questions have occasioned more discussion, and led to less certain conclusions, than that of the actions of the oblique muscles of the eye. As considerable difference of opinion respecting them still exists, and as Dieffenbach's operation for strabismus has invested the subject with practical interest, any facts bearing on the question seem worthy of being recorded.

As exemplifying the different views of the actions of these muscles, taken by physiologists of greater or less celebrity, I may remark that the superior oblique by its contraction was thought to direct the pupil downwards and outwards towards the promontory of the cheek, by Albinus, Cowper, Douglas, Haller,[*] and more recently by Sir C. Bell,[†] Dalrymple,[‡] B. Cooper,[||] and J. Müller ;[§] downwards and inwards by Hildebrand, Gataken, and Dr. Knox; upwards and inwards by F. Müller, Mr. Walker, and (it would appear) by Dr. Franz.[¶]

The action of the inferior oblique was considered by Albinus to be that of rotating the eye so as to direct the pupil towards the temple,[**] and directing the pupil upwards. Meckel thought it directed the pupil downwards and inwards; Hildebrand and F. Müller upwards and inwards : Sir C. Bell, Dalrymple, and J. Müller, are also of this last opinion. Dr. Knox states, as the result of his experiments on the dead body, that " the obliquus inferior, when acted on alone, directed the pupil upwards and outwards, bringing the eyeball itself forwards." In his Anatomist's Vade Mecum, lately published, Mr. W. J. E. Wilson thus expresses himself : " The inferior oblique, acting alone, rolls the globe outwards and upwards to the upper and outer angle of the eye."

With respect to the conjoint action of the two oblique muscles, anatomists are

¶ MEDICAL GAZETTE.
** Lancet, vol. xxxvi. p. 492.

not less divided in opinion. Cowper, Winslow, Morgagni, Cheselden, and Haller, thought they served to keep the eye suspended in the orbit, antagonised each other, and acting vigorously caused the eyeball to project. Dr. Knox considers them simply as antagonists to the recti, which would otherwise retract the eye, and found that, when shortened together, they pulled the eyeball forwards, and directed the pupil downwards and inwards. Prof. Müller also states that when both oblique muscles act together, the eye is drawn forwards and the pupil directed inwards.[*] Sir C. Bell says, " Their combined action draws the eyeball towards the nose."[†] On the other hand, Mr. W. J. E. Wilson states that "both muscles acting together draw the eyeball forwards, and give the pupil that slight degree of eversion which enables it to admit the largest field of vision."

Sir C. Bell and Dr. Quain[‡] deny that they antagonise the recti, because they exist in animals in which the globe cannot be retracted, and are not more developed in those which possess an additional special retractor muscle. The first objection seems only to prove that to antagonise the recti is not the sole function of the muscles, and that it may not be one of their uses in animals where no mechanical impediment to the retraction of the eye exists. Nor does the addition of a special retractor muscle of necessity demand increased development of its antagonists; the latter are not required to overcome the voluntary retraction of the globe, but only during the absence of such action to suspend the eye, and prevent it from being drawn backward by the tonic contraction of their opponents. Mr. B. Cooper found, on dividing the oblique muscle both in rabbits, that there resulted permanent retraction and depression of the globe on the floor of the orbit. Sir C. Bell enters fully into the question, and from his experiments considers it proved that the division of the oblique muscles does not in any degree affect the voluntary motions of the eye; but that the obliqui perform all the involuntary revolving motions so essential to the due preservation of the organ. He considers that the recti, being voluntary

muscles, and inactive during sleep, and that the involuntary obliqui are then acting alone; and he accounts for the upward and inward direction of the pupil during sleep, by supposing that the fourth nerve causes, " on certain occasions, a relaxation of the muscle to which it goes;" and having found that in the monkey the upward and inward motion, which accompanies winking, was more rapid after division of the superior oblique, such relaxation of the trochlearis would favour, he conceives, the natural action of the inferior obliquus. Mr. Dalrymple, on the other hand, views the superior oblique as a voluntary muscle relaxed together with the recti during sleep, whilst the inferior oblique only is involuntarily contracted, and carries the pupil upwards and inwards, " which is found to be the case, when, from whatever cause, the exercise of volition upon the other muscles is suspended." Mr. Hunt, in 1836[*], published a very ingenious paper, in which he offered a rationale of the fact of the orbital muscles receiving nervous energy from so many different nerves. In 1838, Dr. Baly's admirable translation of Müller's Physiology appeared, and at p. 930, the explanation offered of the muscular nerves is very similar to that of Mr. Hunt. The two motores oculorum only are consensual in their action ; the two levators of the globes always act together ; never, naturally, one without the other ; so likewise do the adductors and the depressors ; whereas the eyes are dissociated in their movement outwards, and hence, as the obvious and direct abductor has a special nerve, it is à priori probable that, of the two oblique muscles, that which has a special nerve should be the one designed for dissociate action ; that supplied in common with the consensual muscles, the one for associated movement ; an argument against those who hold that the superior oblique can singly adduct one eye to correspond with the abduction of the other.

Whilst instituting some experiments on the nerves which pass into the orbit in the dog and cat, I found, in reference to the muscles, the following results :— The animal being stunned, and its skull opened, the nerves operated upon being carefully isolated, two needles were

---

[‡] Elements of Anatomy.

[*] Transactions of the Provincial Medical Association.

inserted into each nerve at a slight dis-
tance from each other. When the
opposite wires of a moderately powerful
galvanic apparatus were applied to the
needles, muscular action was induced.
The action was not a sudden firm con-
traction, persisting without relaxation
as long as the connection of the wires
and needles was kept up, but a quiver-
ing motion of the globe in a dif-
ferent direction resulted, as if the
muscle in action were submitted to a
series of repeated small irritations.
Separation of the nerves at their origins
from the brain did not immediately
destroy the irritability of the muscles,
but in a cat, after it had been killed by
division of the spinal cord between the
first vertebra and the occiput, and in
a dog poisoned by a large dose of hy-
drocyanic acid, I was unable to excite
contraction by applying galvanism either
to the nerves, or the muscles of the
eyeball themselves, beyond the slightest
quivering, which ceased almost instant-
ly. In the dog, when the portio dura
was galvanised, slight twitching of the
facial muscles certainly resulted, but
not nearly to so great an extent as when
no prussic acid had been administered. *
In the cat, when the needles were
inserted into muscles supplied by nerves
coming from the spinal cord below the
point of division, contraction resulted.

In the instances which afforded de-
cisive results the following occurred :—

1. The needles being inserted into
the ophthalmic division of the fifth
nerve of the right side, the right eye
was moved quickly by different orbital
muscles alternately, and the lower jaw
was slightly moved.

2. This nerve being divided at its
origin, and separated from the rest, and
the galvanic poles again applied to the
distal portion, no action resulted.

3. The third nerve was separated
from the brain into the end next to the
eye ; the needles were inserted; a brisk
quivering motion followed. The pupil
was now directed upwards, now down-
wards, then inwards, and occasionally
turned with a semi-rotatory motion
upwards and inwards beneath the inner
canthus ; these several motions occur-
ring in quick succession.

4. On galvanising the fourth nerve
the pupil was quickly directed down-
wards and outwards, to attain which
position it swept round the lower lid in
a somewhat revolving manner, and was
not drawn, as it were, in a straight line
to the axis at which it arrived.

5. On galvanising the sixth nerve the
globe was drawn outwards and retracted,
and the haw protruded.

The contraction of the orbital mus-
cles, which followed stimulation of the
fifth nerve during its connection with
the brain, was either fallacious, depend-
ing on the needles touching the con-
tiguous third nerve, or else was owing
to reflex action through the brain. It
evidently proves nothing in favour of
the fifth supplying motor influence to
any of the structures of the eye, as the
effect certainly ceased when the nerve
was separated from its origin, and could,
therefore, be more effectually isolated.

It may not be deemed irrelevant here
to notice some slight peculiarities in
reference to the anatomy of the ophthal-
mic portion of the fifth in the dog and
cat. The lenticular ganglion is situ-
ated farther from the optic nerve than
in man, and is formed exclusively in
the third nerve. The third nerve, im-
mediately on entering the orbit gives off
its branch to the levator palpebræ, and
that to the superior rectus ; passing
forwards, the remaining trunk termi-
nates by dividing into three nerves for
the internal and inferior rectus, and
inferior oblique respectively. Just be-
fore this threefold division, the lenticu-
lar ganglion projects like a small knob
from the upper part of the nerve. In
size about as large as two pin-heads,
it furnishes superiorly a nerve about
two lines in length, which is directed
upwards, forwards, and inwards, to the
optic nerve ; it here divides into two
fasciculi of ciliary nerves, one lying
inferior and external, the other superior
and internal to the optic. To the latter
set become applied two long slender
filaments from the nasal nerve ; they
do not appear to combine, but only to
run together to their common destina-
tion. In no dissection, however care-
fully conducted, generally under water,
could I find a root from the nasal nerve
to join the ciliary ganglion. The
naso-ciliary filaments are white and
firm, though exceedingly slender, and
may be traced as far back as the gas-

---

* Does not this diminution of muscular irrita-
bility account for the sedative effects of hydro-
cyanic acid as a remedial agent in allaying
spasm ?

serian ganglion, without any further con-
nection with the nasal branch than lying
in the same neurileme. I was unable
to find any filament directly from
the sympathetic to the lenticular gan-
glion, but just below the termination of
the naso-ciliary filaments in the gas-
serian ganglion of the dog, the sixth
nerve sent to the ophthalmic a large
twig directed from behind forwards, of
the same colour and consistence as the
nervous twigs which, a line posteriorly,
it had received from the cavernous
plexus of the sympathetic. Very evi-
dent grey nerves are seen passing into
the under surface of the ganglion of the
fifth, in a preparation from the human
subject, and also in another from the
dog, which I dissected. The nerve to
the inferior oblique is the longest of
the three terminal branches of the third
nerve, and in both cat and dog, in its
connection with the ophthalmic gan-
glion, it is very markedly different from
the others : it appears to come off from
the lower part of the anterior margin
of the ganglion itself, which is not the
case with the rest : it gives off no
branches before its entrance into the
belly of the inferior oblique ;—a circum-
stances, I think, favouring the opinion
of Dalrymple as to the inferior oblique
being the only truly involuntary mus-
cle of the orbit.* The internal rectus
of the left eye was divided for conver-
gent strabismus. Twenty hours after
the operation, when the woman looks

straight before her, the axes of the two
eyes perfectly coincide. When the
right eye is directed outwards, the left
remains with its pupil in the centre.
When the right eye is directed towards
an object at the root of the nose, the
pupil of the left is also directed upwards
and inwards, but not inwards quite to
the same extent as the right eye. When
desired to look at the tip of the nose,
the pupil of the left eye is directed
downwards and inwards. If the sound
be closed, and the left pupil directed
inwards as much as possible, the pa-
tient is conscious of considerable effort,
and the maximum of inversion still leaves
some conjunctiva visible between the
cornea and semilunar fold, which, of
course, is not the case on the sound
side ; so that the power of direct inver-
sion, though slightly possessed by the
left eye, is very different in the two
eyes.

There is every reason to suppose that
the internal rectus was here entirely
divided ; the tendon was completely
over the blade of the scissars, and ap-
peared without any adhesions farther
back : before the cut was made the eye
immediately started to its proper axis,
and is not inverted by merely directing
the opposite eye outwards, which would
certainly ensue were the internal rec-
tus in tact, as exemplified in another
case where some of the upper fibres of
the tendon escaped division. What
muscle, then, effected the inward move-
ments to the degree in which they
remain ? Some would answer, the supe-
rior oblique alone, others the inner
fibres of the rectus superior or inferior,
according as the upward or downward
direction predominated. It is not proved
that part of any muscle of the eye can
act without the whole, and if the view
that I have been endeavouring to sub-
stantiate be correct, the superior oblique
alone cannot be the agent. Do not
the remarks which have preceded jus-
tify the conclusion, that the motions in
question may be ascribed to the joint
contraction of both obliqui, combined
with the superior rectus in the upward
and inward motion, with the inferior
rectus in that downwards and inwards ?

Manchester Royal Infirmary,
October 5, 1840.

* Though not strictly pertinent, I may mention
that in neither dog nor cat did I find a distinct
lacrymal nerve from the first division of the fifth,
but two long nervous filaments passed upwards
and outwards along the outer part of the orbit,
and supplied twigs to the lacrymal gland and fat
and integuments near the outer canthus, one (sub-
cutaneus malæ) passing through the check-bone.
Just anterior to their origin from the second
division of the fifth, that trunk receives organic
filaments which pass from before backwards
from the spheno-palatine ganglion. This gan-
glion is a flat, elongated, oval nervous mass, lying
on a muscle anterior and internal to the infra-
orbital trunk, with which it is only connected
by means of filaments which pass from the gan-
glion to join the different branches. The ganglion
sends backwards and inwards twigs to the soft
parts, and to the mucous membrane at the back
of the pharynx, backwards and outwards to the
infra-orbitar nerve and downwards small fila-
ments, which become united to those twigs of
the infra-orbitar nerve, which are distributed to
the teeth, back part of the roof, the mouth, and
soft palate. Does not the fact of the palatal
nerves in the dog being more especially furnished
by the second primary branch of the fifth, and
not coming, as in man, from Meckel's ganglion,
support Dr. Alcock's view of the posterior pala-
tine nerves being partly gustatory?

ANALYSES and NOTICES of BOOKS.

*A Practical Treatise on the Diseases
peculiar to Women. Illustrated by
Cases, derived from Hospital and
Private Practice.* By SAMUEL
ASHWELL, M.D., Obstetric Physician
and Lecturer at Guy's Hospital.
Part I. Functional Diseases. London:
Highley, 1840. 8vo. pp. 208.

IF Dr. Ashwell's opportunities for
practical observation were exclusively
confined to the extensive Lying-in
Charity of Guy's Hospital, he would
have "ample scope and space enough,"
either to correct or confirm the prevail-
ing doctrines as to the nature and
management of female diseases. And
as we know no reason why we may not
for once depart from the common
custom of ending a notice of a work
with the reviewer's opinion of its merit,
we begin by saying that he has made
good use of his opportunities. It is
true that this treatise is not remarkable
for any novelty of views, but it is sound
and sensible in its doctrines, and
therefore reflects credit upon the writer,
and well deserves the perusal of the
junior practitioner.

Dr. A. proposes to arrange the
diseases peculiar to women in three
great divisions. In this, the first, he
places the functional. In the second
we are to have the organic diseases:
and, in the third and last part of the
work, will be comprised the affections
of the pregnant and puerperal states.
The subjects treated in the first part
are chlorosis, with cases, amenorrhœa,
emmenagogues, dysmenorrhœa, pro-
fuse menstruation, menorrhagia, leu-
corrhœa, and inflammation of the cer-
vix uteri; affections attendant on the
decline of the catamenial functions.

The chapter on chlorosis is brief and
practical, and, as far as our experience
teaches us, correct both in the descrip-
tion of the disease and its mode of
management. We think with Dr. A.
that it may be fairly assumed that chlo-
rosis primarily depends on a morbid
condition of the blood, which secon-
darily affects the ovaries and uterus, by
retarding their growth. This opinion
is supported by the fact, that in the

blood of chlorotic patients there is an
increased proportion of the serum, with
a marked diminution of the crassamen-
tum. It would not be difficult to trace
to this morbid condition of the blood
many, nearly all, the different theories
which have been propounded. Andral's
remarks on the anæmia of chlorosis are
quite confirmatory of Dr. Ashwell's
views. The leading and most frequent
complications of chlorosis with func-
tional derangement of different organs
are clearly and usefully described. In
the general plan of treatment too we fully
concur. "The treatment of chlorosis
to be extensively successful must be
early and most seduously prosecuted."
The treatment of the most common
form of chlorosis, namely, that accom-
panying puberty, may be regarded as
the type of the treatment of all the
others, embodying the principles which,
with greater or less modification, are
universally applicable. "It is here, at
the very threshold of the disease, when
its character is not understood, or when
it is treated empirically, that the great-
est error is committed. It is viewed as
a local, not as a constitutional affection,
and many are the individuals who have
been sacrificed to the vain and ignorant
attempt of prematurely establishing
menstruation: mercury, drastic purga-
tives, and emmenagogues, have irre-
trievably destroyed the constitutional
power, and paved the way for phthisi-
cal disease." Electricity, Dr. A. says,
deserves to be mentioned as a local
uterine stimulant. He has seen many
cases where its efficacy was decided.
We have not been so fortunate; we too
have tried this agent, and we believe
in appropriate cases, without either
harm or benefit. Sixteen cases of
chlorosis are briefly detailed. The se-
cond chapter, on amenorrhœa, contains
a good practical sketch of this disease
as it occurs in different constitutions.
The remarks on the limits within which
the employment of emmenagogue
remedies ought to be restricted, offer a
useful lesson to young practitioners, of
which we know, from abundant expe-
rience, they often stand in need. With
some, stimulant vaginal injections are
quite the fashion. We hear much of
their curative powers, but nothing of
their danger. But they are not safe
remedies where there is uterine conges-
tion. In two such cases dangerous in-

flammation of the cervix uteri and upper part of the vagina followed their use. Stimulating fluids have been, as emmenagogues, injected into the uterus. Death, from peritoneal inflammation, has several times followed the practice, and in two instances which were witnessed by Dr. Ashwell fatal results had nearly ensued from most alarming attacks of this formidable malady. There is no danger, and more promise of benefit, from stimulating injections being thrown into the rectum. Dr. A. has used, with advantage, the favourite enema of Dr. Schonlein : ten grains of aloes, and one ounce of mucilage, twice or three times a day. Mercury is our most powerful deobstruent, if judiciously managed.

Of the ergot of rye as an emmenagogue, Dr. A. "cannot speak favourably :" neither can we, nor can we perceive that it is " on principle easy to understand how it should produce such an effect." Iodine is, occasionally, a good emmenagogue, but it has frequently failed in our author's practice. The remarks on vicarious menstruation, and on the other subjects we have above mentioned as forming the contents of the work, are practically good. This first part of Dr. A.'s work is a very favourable specimen of his ability, and we doubt not, when it is concluded, that it will fairly add to his reputation.

Elements of Materia Medica ; comprehending the Natural History, Preparation, Properties, Composition, Effects, and Uses of Medicines. Part II. The Vegetable and Animal Kingdoms. By JON. PEREIRA, Esq. F.R.S. &c. &c. Longman & Co.

WE have pleasure in being able to announce the second volume of Mr. Pereira's Elements of Materia Medica, which completes the work : comprehending the Vegetable and Animal Kingdoms. It is executed in the same style and manner as that which appeared last year. The mass of information it contains is immense, constituting by far the most complete system of materia medica which has been published in this country. It cannot fail to become a standard work.

PROGRESS OF THE PROFESSION.

IN speaking last week of the condition of the Medical Schools as an evidence that the present number of practitioners is, in proportion to that part of the population who can remunerate them for their attendance, in excess, we expressed an opinion that the evil would remedy itself, and was, in fact, even now in progress of being removed. If this opinion be, as we have no doubt it is, correct, it is fortunate ; for as evils of this kind, like the diseases of the body, rarely remain stationary, but tend, with more or less rapidity, to recovery or destruction, another result, worse than the temporary evil which has happened, might have been threatened. It might have been that there would take place no reduction in the number of the members of the profession, (such as we said last week was evidently indicated), but a reduction of their respectability. For it is clear that even the smaller remuneration which is now afforded to the average of practitioners would be sufficiently attractive to persons in a lower grade of society, who, if they could gain admission into the ranks of the profession on easy terms, would find there both an increase of their respectability and a good return for their trouble and small expenditure. There could be, in the case of an excess of practitioners, only one alternative—either their numbers must be gradually reduced, or their station in society. The latter has happened to many honest callings which, from being once deemed honourable, have now fallen into dis-

repute ; the former is happily the course which the mischief in our case has chosen for itself.

It is probable that for this fortunate result we may principally thank the increased demands for general and professional knowledge which have been made upon the candidates for professional dignities, and, as necessarily connected with these demands, those for an increased expenditure of money. It is, we know, a favourite theory with many, that the roads to professional practice should, like those to eminence in learning, considered abstractedly from its application in earning money, be open and unobstructed to all, without respect to rank or pecuniary means ; but it is surely not going too far to say, that had they been so for only the last twenty years, the medical profession would, by this time, have been irrecoverably depressed. With no increase of general profits, but a still greater surplus than actually exists of those who have to divide them, it is impossible but that its members must have been degraded from the deservedly high station which they now hold in society.

Reflecting on the conclusion that the medical profession was still likely, in successive years, to continue rising in the scale of society, both scientific and political, our attention was naturally drawn to the progress which its several ranks have made since their first origin. It can never harm or annoy any honest man, who has gradually raised himself in society, to look back upon the condition in which he was born and bred ; nay, it has been said by one who spoke well on all such subjects, that the most intense enjoyment of which the human mind is capable, is that of a man who, having been exalted for his virtues, returns to the home of his childhood, and contemplates all the scenes that were familiar to him in his early

days. It should be the same with every one who, in an honest *esprit de corps*, considers the history of his calling ; he should feel pride at every upward step it has honestly made, and should look with sorrow on every past, or probable future, degradation.

The gradual rise of the medical profession has, indeed, been most remarkable, and is, we believe, without parallel in any other profession or trade. Who, for example, could believe that the apothecary of the present day is a lineal descendant from those of two centuries ago, whom he now resembles only in name ? Many amongst us (*loquitur apothecarius*) have probably forgotten that our forefathers associated with the men of so ungentle a craft as the grocers, and were so little removed in rank from them that their common company was not named after what we should think must have been its better members, but was called indiscriminately the " Grocers or Poticaries' company." Nor was it till the reign of the sagacious and learned James the First, that a king could be brought to determine of " his own wisdom and mightiness the propriety of separating" the two classes, and in order " to promote the full dignity of the faculty of the pharmacopolites, before sunk into disrepute, and despised," to grant that all the freemen of the old company, who were educated in and practised pharmacy, should constitute a distinct corporation, and be called by the name of the Master, Wardens, and Society of the Art and Mystery of Pharmacopolites of the City of London.

Such was the origin of the Apothecaries' Company ; once identified with Grocers, whom they have now left so far behind, as to make room for the introduction between them of another class, the chemists and druggists, who now perform some of the higher offices of the medical profession, in addition to

all those that were at first discharged exclusively by the apothecaries.

But probably many who have had to do with the Pharmacopolites' Company are unaware that the licentiates, are a class which was only of late years appended to the society, and which still forms no essential part of it. It was only by degrees that the members of the Company rose from being the dispensers and administrators of the prescriptions of the physicians; nor could they exalt themselves even so high as the station of the chemist of the present day, till one of their most worthy predecessors, William Rose, in 1703, after suffering three several defeats in the Court of Queen's Bench, obtained a reversal of that Court's judgment in the House of Lords, and had it established for ever that an apothecary may make up and administer medicine for a patient without any license from the faculty, and without the direction of any physician.

So great a right being gained did not fail to make this branch of the profession infinitely more attractive than it had hitherto been ; and from the time when it was obtained, the apothecaries might be reckoned as sure of enrolling the greater number of the members of the common profession. But the facility of admission into a station which conferred so much advantage at so small an expenditure would have endangered its reputation, had not the bill of 1815, by excluding all who had not proved that they merited a license to practise, secured the respectability of the class, by fixing for its members a certain standard of knowledge, and so indirectly, of education and pecuniary means. Defective as in many respects it undoubtedly was, the bill of 1815 deserves to the full the credit of having, by the introduction of a new class, the Licentiates, secured to the Company the association of a body of gentlemen, by

whom its character might be known and appreciated, not as before, only in and near London, but throughout the kingdom.

The next most important advance must be in the recollection of most of our readers—that, we mean, by which it was determined that an apothecary might not only prescribe the medicines he should himself administer, but might receive an adequate remuneration for that which is to him of yet more importance, his time and the exertion of his talents. Thus, then, from being the companions of grocers, apothecaries have, in two centuries, raised themselves to privileges and an estimation scarcely short of those of the physicians, and differing from theirs in degree rather than in kind. The progress having been made honestly, there can be no pain felt in looking back on it; it has been the result in part, and perhaps most visibly, of the energy and public spirit of a few, but in a still greater, though not so evident a degree, of the gradual increase in the amount of education which has been from time to time, and especially of late years, required of the candidates for the license of the Company.

The rise of the surgical branch of the profession has not been less remarkable, commencing, as it probably did, from even a lower grade, that of the barbers and blacksmiths, who were occasionally called in to perform the chief brutalities of monkish surgery, and having attained to the enrolling among its members many of those who have in the most eminent degree advanced the whole science of medicine. But its story is too well known to need repetition; Hunterian orations and introductory lectures have made the guild of barber-surgeons, the separation of the latter class, and their first and subsequent charters, matters of common knowledge. It is sufficient

to say here, that the elevation of this, as of the preceding branch of the profession, has been purely the result of constantly maintaining a standard of knowledge among its members proportionate to, and always far above, the constantly increasing improvement in the condition of the world at large. And this must ever be the principle upon which future progress will be secured; that to the large mass of the world high intellectual standard is indirectly a money-standard; it demands from the great majority of men a high amount of education, such as cannot be obtained without considerable expense, and can be dispensed with only by those few whose eminent talents would ennoble them in whatever station they might move, and would, more worthily and certainly than money alone, raise them from the lowest to the ... have ... highest rank.

That an increase of knowledge is sure to be associated with, or followed by, an increased social elevation of the members of a profession, is proved further in our case by the fact that, without such an increase, those who started fair with us have remained stationary, or have retrograded. With grocers, blacksmiths, and barbers, the medical profession no longer holds fellowship; they have long since ceased to regard us as relations, great as would be the honour conferred upon them by the connection. In conclusion we may remark that, of those who practise physic, one class still remains at the same level of degradation in which it has ever lain—the quacks, in all ages an uneducated, ignorant, and dishonest set of men, whom no ill-gotten wealth has ever been able to convert into gentlemen, and who have never, though they have fed upon the credulity of the world for centuries, attained to the possession of the smallest share of the respect even of their vic-

tims. Such they must remain; money though they may earn it largely, will never give them rank; their ignorance, and their consequent need of concealing it by impudence and fraud, must always neutralize all the advantages it might offer; and even Mr. Warburton's measure, if he could carry it, and give them a kind of side-wind license, would only make them registered impostors.

ON RAPE AND ITS PUNISHMENT.

THE following passage occurs in the last number of the Quarterly Review, in an article on the "Life of Sir Samuel Romilly." After some observations against the total abrogation of capital punishment, the reviewer says, "To this general suggestion we beg leave to add one word on the bill lately introduced by Mr. Fitzroy Kelly. We were exceedingly surprised that the principle of *generalizing*—which, in the diversity of human nature, is sure to produce anomaly—should have rendered that honourable and learned ... but ...tant to admit exceptions ... ...eers murder and high ... will more surprised even in the cases of ... not added as treason; but we are still well aware that the case of *rape* was ...ny accu... a third exception. We are ... and we of the suspicions to which ma...treme sations of this class are liable, ...con... do not quarrel with the almost ex... on reluctance of judges and juries to ...nd vict in cases which, in general, rest... that a person liable to the strong... interests and influences that can wa... human testimony. Of such dubio... cases we do not speak, and, in practice we venture to assert that they are safe... intrusted to the jealous discretion of th... jury and the judge; but for cases o... real and indubitable violation, where what is lost is more precious to the individual, and more important to society, than life itself—which, in certain cases, must involve husbands and children in irredeemable and unredeemable misery ——we do say that against such a crime— being, in its immediate motives, stronger, and in its consequences more frightful, than murder—an equal protection should be given. It would speak little for the feelings or the morals of a society where the honour and purity of women should be guarded under no

higher sanction than a spoon or a snuff-box *."

Our regard for truth and justice induces us to touch upon a few points which the reviewer has totally overlooked.

The first is, that the weight of medical evidence, as well as of common sense, is against the possibility of rape in the great majority of instances. On this point the reader may consult the authorities quoted by Beck (Elements of Medical Jurisprudence, fifth edit. p. 90, et seqq.) For instance. " Metzger only allows of three cases in which the crime can be consummated — where narcotics have been administered— where many are engaged against the female — and where a strong man attacks one who is not arrived to the age of puberty."

The reviewer, indeed, does not object to the acquittal of the prisoner in what he calls " dubious cases ;" but, then, the truth is, that these cases, so far from being dubious, are the clearest in the world ; they are the ones in which the prosecutrix is guilty of flat perjury. The books are full of instances where the prosecutrix was ready to sacrifice a man's life with the hope of patching up her reputation for a time, but where her case broke down under the incredible absurdity of her own evidence. These are pure fictions. " For one *real* rape that is met with at the assizes a dozen or more *sham* ones are preferred †." This is, no doubt, true ; but are the convictions only one in thirteen ?

The " dubious cases" are the majority of those in which conviction takes place, where the woman merely exaggerates the amount of her resistance, and persuades the jury, as she has persuaded herself, that she did the utmost to prevent the loss of her honour.

Secondly, the reviewer, in a previous page, quotes the following passage from a letter of Sir Samuel Romilly's. " I am much obliged to you [Roget] for giving me your sentiments on the question, whether any crime ought to be punished with death. The objection you make to the punishment of death, founded on the errors of human tribunals, and the impossibility of having absolute demonstration of the guilt of a criminal, strikes me more forcibly

than any argument I have ever before heard on the same side of the question." Sir Samuel Romilly did not go so far as his correspondent, though admitting that the argument had great weight. But if this argument is powerful, when applied to other offences, where the evidence is as strong as human frailty can afford, what must it be when applied to a crime which the best judges allow to be barely possible ; where the only evidence is that of a single person, " and that a person liable to the strongest interests and influences that can warp human testimony ;" and where the prosecutrix so often yields to the temptation, that twelve accusations out of thirteen are sham ones ? For this, therefore, above all other crimes, it is necessary to have a revocable punishment.

After all, much must necessarily be left to the discretion of the prosecutrix ; for it would be impossible for the most acute legislator to define the boundary between that slight resistance which is the last compromise between instinct and modesty, and the real struggles of indignant innocence. But under a mitigated code, if the complainant should misstate the transaction, it will be gratifying to herself, as well as to society, that the error is not irredeemable, and that life has not been sacrificed to her resuscitated modesty. At the worst, after some years of seclusion, the prisoner will come forth a wiser man ; and in doubtful cases her character will have been established by the solemn sentence of the court.

If a complete abrogation of the penalty of death for rape should seem dangerous, the exceptive cases which we quoted above from Metzger might still be liable to the punishment.

Lastly, the reviewer speaks as if female purity would be unsafe if rape were not punished by death. We believe that there is no other country in Europe where it is supposed to require this protection ; and moreover, that no execution for this crime has taken place in England for several years.

MR. WARBURTON'S BILL.

[WE very readily give insertion to the subjoined letter from Dr. Crosse, although we have the misfortune to differ from our respected correspondent.— ED. GAZ.]

Sir,

I am a constant reader, and hope to be excused for addressing you in opposition to some of the sentiments expressed in the last two numbers of your journal. Residing in the provinces, and acquainted with the state of the medical profession from extended observation, as well as lengthened experience, I have arrived at the conclusion that its present distracted and unprotected condition calls for legislative interference. In common with numerous members of our fraternity I have looked anxiously for Mr. Warburton's bill; and now that it is put forth, I am not less anxious that it should be deliberately and candidly discussed.

You will pardon my boldness in remarking, that you seem determined, by having the first blow, to endeavour to put down this proposed bill *in toto*—to strangle it in its very birth beyond the possibility of resuscitation, as if it contained nothing calculated to meet the wants of either the community or our profession. It will be the duty of every practitioner to peruse the whole bill ere he makes up his mind as to the value of its numerous provisions. Hitherto I have only seen an abstract; but this has sufficed to enable me to form an opinion upon some points. It may, indeed, be said that there are two bills: the one which takes precedence, extending to Clause 18 inclusive, and to which alone I beg to direct your readers' attention at present, relates to " registration of all qualified members of the medical profession" upon a uniform plan, in the whole of the United Kingdom. Are you, Mr. Editor, so kind as to assure us that such a registration is not required ? or do you object to the plan by which the present bill seeks to accomplish the desired purpose ? I confess that, looking generally at this registration bill, without entering minutely upon each clause, I think it is admirably suited to benefit the profession.

Our brethren are all convinced that the legal profession knows much better how to take care of itself than the medical ; yet it is heavily taxed for registration, each practising lawyer in England being compelled to pay *eight pounds* annually for his license ; and

the large sum thus raised does not go in support of any privileged corporate body, but to the public revenue. If lawyers are content to be thus taxed, we may be sure there is some good in it ; and I trust your readers will remember this, and not take alarm at your outcry about being " taxed to purchase chains for themselves." With about fifteen thousand medical men in England, and nearly as many in the rest of the empire, a tax so small as to be only nominal will suffice.

Before concluding, I must beg you to allow me to reiterate, that, in my humble opinion, a registration of all qualified members of the profession is a first and important desideratum : it should apply to the entire of the United Kingdom ; and can only become efficient by being annually renewed and published : and since medical attendance must be regarded as a necessary, not a luxury, required by the poor as well as the rich, no higher tax should be imposed than will meet the expenses of carrying into effect and sustaining the measure. These and many other valuable conditions are intended to be fulfilled by the registration clauses of the " Medical Profession Bill," which, however it may be received by our medical corporations of all grades and sorts, will, I have reason to believe, meet with deliberate and serious consideration from the great body of provincial practitioners.

I beg to subscribe myself, sir,
Very obediently yours,
JOHN GREEN CROSSE.

Norwich, Oct. 12, 1840.

CLINICAL LECTURES,

By W. DAVIDSON, M.D.,

One of the Physicians to the Glasgow Royal Infirmary, and Lecturer on Materia Medica.

Effect of various tests on the urine in Diabetes Insipidus—Treatment. Diabetes Ureosus —Remarks.

DIABETES INSIPIDUS.

HENRY LEVI, admitted 18th of January, 1840, æt. 24 : Polish Jew, hawker, of full and flabby habit of body. Complains of soreness and weakness in back and lower extremities, great thirst, and general debility. Appetite voracious, and he has frequent calls to void urine, as often as every half hour ; perspires none, and is losing flesh

rapidly. Urine, to-day, amounts to 20 pounds, specific gravity 1006, of a pale straw colour, has very little taste and a slight odour. First observed complaint about seven months ago, after exposure to cold and wet, while fatigued. Five months ago, he states that his urine was diminished to nearly its natural quantity by the use of opium. In this case the disease is characterised by many of the usual attendant symptoms, viz., weakness in back, loins, and extremities, particularly his knees, which are often very painful; excessive thirst, voracious appetite, frontal headache, constipation, diminution of the physical weight; he also complains of confusion of head, and loss of memory. He is still of rather a full habit of body, and his skin is soft and smooth. His urine was of specific gravity 1006, on his admission, and it still ranges about the same, being more generally 1007, while it was once or twice as low as 1004. Its quantity is generally from 18 to 20 pounds, but a few days after his admission it amounted to 28½ pounds; it is almost as colourless and transparent as water, has a slightly saline taste and urinous odour, deposits a very slight flocculent precipitate on standing for several days, and gives out an ammoniacal odour. No deposit is produced by heating it, or by the addition of nitric acid; it does not affect litmus or turmeric paper. Iodic acid and gelatinous starch, when added to it, cause, in a short time, a purplish colour, which gradually deepens into a purplish blue tint; but by no means so deep as that produced in the healthy urine by reagents. 1000 grains of his urine were evaporated to dryness, and the extract amounted to 8·2 grains; of this 5·0 grains were dissolved in three successive portions of alcohol. He was passing daily about 20 pounds of urine at this period; now, upon this calculation, the amount of solid matter passed in twenty-four hours would be 944 grains, while, according to Dr. Thomson's analysis, if the solid constituents of the urine be about 42 in 1000 grains, and the average diurnal quantity be 3 pounds (36 ounces), there ought to be only 725 grains of solid extract.

Mr. M'Gregor found the diurnal quantity of urea, in a healthy person, to be 428·5 grains, which he considered, however, rather beyond the healthy standard: now by calculation this patient must be passing daily 576 grains of urea, which is considerably above the average proportion, and will nearly account for the extra quantity of solid matter contained in the daily amount of urine, for in other respects it appears quite natural in chemical constitution. Does this case, then, belong to that class of diseases which are characterised by a great increase of urea, in the urine, named by Dr. Willis, in his excel-

lent work, azoturia, or is it merely a variety of hydruria, where the only thing abnormal in the urine is a great increase in the quantity of aqueous secretion, but where the proportion and quantity of its constituents are natural? The specific gravity of ureous urine is generally high, although there are recorded exceptions to this rule. Dr. Willis states that it ranges from 1018 to 1035; but he quotes a case related by Mr. Rees, in which it was only 1008, and where the extract from 1000 grains amounted to 15 grains, of which 10·2 were urea. This patient's disease seems to be of the same nature as the last case alluded to, and it is probable that it is merely a variety of hydruria; for the increase of urea is not very excessive; and though it must tend to debilitate the patient by the extraction of an extra quantity of nitrogen from the system, yet certainly no very serious weight can be attached to this consideration. The prognosis, however, of this affection is certainly more unfavourable, in as far as the urea exists in abnormal quantity; for such diseases produce a more decided impression on the constitution than simple hydruria, although neither of them are incompatible with a considerable term of life.

Treatment.— As there are some reasons for believing that, in this disease, as well as in diabetes mellitus, the digestive organs are in a state of derangement, a primary part of our treatment was attention to the stomach and bowels. His diet was, therefore, regulated, and it consisted of soup without vegetables, a moderate allowance of animal food, farinaceous substances, and milk. The quantity of food was also restricted to about 22 ounces of solids, in order that the digestive organs might not be burdened with more labour than they were capable of performing, while, at the same time, a sufficient supply of nutriment was furnished to the system; and as his residence in the hospital exposed him to no corporeal tear and wear, this amount of food was calculated to be about enough. He also attempted to limit the quantity of his drink to six pounds, but on several occasions found the discrepancy between his ingesta and egesta so enormous, that there seemed no possibility of explaining it on any other principle than that he had stolen an additional supply of water. This restriction was, therefore, abandoned as impracticable.

When first admitted, he had several purgatives of castor oil and calomel, and his drink was acidulated with aromatic sulphuric acid, and, in order to determine to the skin, he was ordered the warm bath every second night. As he complained much of frontal headache and loss of memory, his head was shaved, and afterwards a blister was applied to the nape of the neck. He was also

ordered, on the 31st of January, the follow-
ing combination of gentian and opium :—

   R Infus. Gentian, ℥biss. ; Tinct. Opii,
      ℥ss. M. Cap. ℥iss. ; misturæ sexta
      quaque hora.

As the urine was still about 18 pounds,
and as very little impression had been made
on the disease, the quantity of laudanum in
the mixture was increased to an ounce, and
a blister applied to the nape of the neck on
the 6th February.   From this time the
urine began to diminish in quantity ; his
headache was less, his strength was greater,
his thirst diminished, and his tongue was
pretty clean ; but his bowels required the
regular use of the colocynth pill. He was
discharged on the 15th March, nearly cured,
his urine being about 90 ounces of sp. gr.
1011, having a very urinous odour ; but it is
not at all improbable that the disease will
return if he be again exposed to the irregu-
larities of his avocation.

    CASE II. — Janet Chisholm, admitted
22d November, 1839, æt. 27, vagrant, of
ordinary habit of body. This patient was
admitted chiefly on account of a scabious
eruption, which assumed the papular form
on all parts of the body, except the hands,
where it was pustular. This eruption had
existed for about six weeks, was somewhat
difficult to cure, but was ultimately eradi-
cated by the external employment of the
bichloride of mercury. In addition to this
disease it was discovered that she had been
passing for the last eighteen months upwards
of 20 pounds of urine daily ; that she had
been under treatment in one or two hospitals
for this disease, without much benefit ; and
that it had succeeded a diarrhœal or dysenteric
affection, under which she laboured for some
time.

This seems to be a case of hydruria ; for
the urine differs not materially from the
natural standard, except in the increase of
quantity and diminution of solid extract.
The quantity of urine has varied from 20 to
30 pounds, and, on one or two occasions, it
amounted to 33 pounds. Its sp. gr. is
generally about 1003, sometimes 1002 ; it is
nearly as colourless and transparent as
water, has a very slight urinous odour, but
scarcely any saline or other taste. It pro-
duces no effect on litmus paper, does
not depo it any sediment when kept for
several days, but becomes slightly ammonia-
cal.   1000 grains sp. gr. 1003 were evapo-
rated to dryness, and left 2·6 grains of solid
extract ; of this 1·2 were dissolved in three
successive portions of alcohol. The urine
of this patient, therefore, contains a little
less than the half of the usual quantity of
solid extract ; for by calculation 24 pounds,
the daily quantity, contain nearly 360 grains
of solid matter.   The urea, however,

seems to exist in about the normal propor-
tion to the other constituents. We were a
little surprised at this deficiency of solid
matter in the urine, and took the precaution
of procuring some, under circumstances
where no deception would be practised.
When its sp. gr. was taken, it was found to
be 1000 ; but this was, no doubt, owing to
its temperature. The quantity of extract
was also found increased to 3·5 grains in
1000 of urine, when the sp. gr. was 1005
on one particular day. The urine was not
altered in colour by nitric acid, nor was any
deposit produced ; but a purplish tint was
caused by the addition of iodic acid and
starch, indicating the presence of uric acid,
even in the very small proportion in which
it must have existed in this instance. As
far, then, as the constitution of the urine is
concerned, there appears to be nothing more
abnormal than an increase of its watery
and a deficiency of its solid contents. She
has, however, dyspeptic symptoms conjoined
with these, of rather an obstinate character,
though not apparently accompanied with
any danger, viz., dry and furred tongue,
voracious appetite, insatiable thirst, consti-
pation, tumid abdomen ; her skin, however,
is not harsh or dry, nor is she emaciated, or
very weak, as in diabetes mellitus, and her
pulse is nearly natural. The prognosis is,
therefore, not unfavourable, as far as regards
any speedy termination of her life, although,
from the disease having existed for nearly
two years, her chances of a complete recovery
are considerably diminished ; for it is quite
evident that the severe dyspeptic symptoms,
the want of rest, the immense additional
labour given to the system, in freeing it from
the load of water taken into the stomach,
must tend to wear out the strength, or,
perhaps, induce some organic disease.

Treatment. - At first when admitted she
was treated with the warm bath and creosote,
which was carried to the extent of twenty
drops in the day ; but, as no improvement
followed its employment, she was, on 9th
December, ordered pills, containing each a
quarter of a grain of nitrate of silver, and
half of a grain of opium, every fourth hour,
which were continued to the 23d January.
This treatment was adopted partly with a
view of combating the dyspeptic symptoms,
and partly as a fair experiment, in this in-
tractable disease. No particular result
followed its use, although the urine has
never amounted to the same quantity since
it was employed, it being 33 pounds on the
day she commenced with it, whereas since
it has never exceeded 22 pounds. She
was then treated for about a week with
a morphia draught at bedtime, along with
regular laxatives : and on the 30th of January
the acid infusion of rennet (formerly noticed)
was prescribed, in the quantity of one ounce

daily, colocynth pills as a laxative, and 40 drops of the solution of muriate of morphia, mixed with 30 drops of ipecacuanha wine at bedtime. As there was some tenderness in the epigastrium, on the 8th of February a blister was applied to this situation ; and on the 28th another to the back for a similar pain. In adopting this practice the constitutional effects of the blisters upon the system generally, particularly upon the kidneys, were kept in view ; for cases are recorded by authors where revulsion of this kind has been useful. This patient continued the last mentioned treatment up to the 28th of February, when she was dismissed. The quantity of urine at this period was about 16 pounds, sp. gr. 1004, slightly opalescent, deposited a whitish sediment, had a distinctly urinous odour and taste, and became decidedly ammoniacal on standing a day or two ; while in other respects she was greatly improved. It is extremely probable that the mitigation of this disease will only be temporary ; and that so soon as she resumes her vagrant habits, her dyspeptic complaints will return, and with them the abnormal secretion of urine.

DIABETES UREOSUS.

James Simpson, æt. 45, labourer, pretty healthy in appearance, was admitted on the 29th of July, 1840, with the following symptoms : viz., great general debility, heat of skin, which is always covered with a clammy moisture, frequent perspirations on the slightest exertion, and great thirst. For the last four and a half months has required to void urine every half hour, and its quantity is about 9 pounds daily. Urine sweetish, but its colour is nearly natural. Is much stronger, and makes less urine than he did at the commencement of complaint ; appetite keen, countenance good, pulse moderate, tongue clean, bowels constipated.

August 3rd.— Sp. gr. of urine 1010.

R P. Nitrat. argent., gr. xii. P. Opii., gr. xviii. ℳ. Fiant pilulæ xviii. Cap. 1. 6ta. q q. hora. Diet, 12 oz. beef, 12 oz. bread, milk 24 oz.

10th.— Pulse 72, moderate ; tongue white, moist ; bowels were very constipated for several days, but are now open ; thirst and appetite great; urine 3 pounds, of sp. gr. 1940, having a pale yellowish tint, a saline taste, and urinous odour.

14th.— Urine 5 pounds, of sp. gr. 1033, having a urinous odour and saline taste.

16th.— Urine 3 pounds, of sp. gr. 1031, pretty natural in its appearance.

18th.— Urine 8 pounds, of sp. gr. 1034, saline in taste. Diet.— Bread, 24 oz., milk, 30 oz., pease meal, 4 oz.

21st.— Sp. gr. of urine 1027, having a peculiar odour, which is not so urinous as

formerly, and a taste slightly sweetish like whey. It is slightly opalescent ; the quantity is 5 pounds 8 ounces.

22nd.— Urine 12 pounds, of sp. gr. 1025, having a pale straw colour, peculiar odour, and a wheyish taste.

23rd.— Urine 14 pounds, of sp. gr. 1022, slightly opalescent, and having a pale greenish-yellow tint. Diet. — 16 oz. beef, 8 oz. bread.

26th.— Urine 5 pounds, of sp. gr. 1030, having a brownish-yellow colour and saline taste. Beef to be increased to 24 ounces.

27th.— Urine 4 pounds, urinous in taste and odour, and of sp. gr. 1029.

31st.— Urine has a brownish-yellow colour, saline taste, becomes ammoniacal when kept a few hours, and of sp. gr. 1031.

September 2nd.— Urine 4½ pounds, of sp. gr. 1030 : when recently passed it reddens litmus paper, has a brownish-yellow colour, an odour resembling beef-tea, a bitterish saline cooling taste, but is not in the slightest degree sweetish.

31st.— Urine 3½ pounds, of sp. gr. 1030, reddens litmus paper, and has a clear brownish-yellow colour.

REMARKS.— This patient was two or three days in the hospital before he was subjected to any treatment, because we had not been able to ascertain in a satisfactory manner to what species of diabetes his disease belonged. On tasting his urine, on the day following his admission, no saccharine quality could be discovered : on the contrary it appeared to be slightly saline. Two days afterwards, however, it was distinctly sweetish to the taste. A portion of the non-saccharine urine, passed on the first day after his admission, was evaporated nearly to dryness, and afterwards mixed with nitric acid. It crystallized pretty distinctly, nearly throughout the whole mass. The same urine was also mixed with yeast, but no fermentation occurred. As the urine continued, for about three weeks after his admission, to be characterised by a superabundance of urea, his diet was made almost completely vegetable, in order to test the effects of this species of aliment upon the character of this fluid. From the reports taken after this change was effected, it will be seen that the urine became saccharine, and was quite different in its general physical characters. On adding a small portion of yeast to it fermentation was excited, and the liquor became in a few days distinctly acid to the taste, and reddened pretty strongly litmus paper. Even without the addition of yeast it speedily became decomposed, gave out a very fœtid peculiar odour, and reddened very decidedly litmus paper ; but no odour of ammonia was ever noticed during the process. The diet was again changed on the 23rd of August to one

composed chiefly of animal food, and the change which this produced was equally remarkable as in the former case, with what was vegetable. The quantity of the urine was diminished in three days to five pounds, and its sp. gr., although increased, was not very great. It was brownish-yellow in colour, having a urinous odour, a bitterish saline taste, did not ferment with yeast, became ammoniacal, turning turmeric paper brown, after being passed twenty-four hours. The urine of this patient, the saccharine as well as the saline, gave with iodic acid in excess, and gelatinous starch, a deep purple-blue colour and precipitate, after being mixed together for about an hour ; indicating the presence of uric acid in about the usual proportion. This experiment also tends to prove that the quantity of sugar in the sweet variety of urine was not very great ; as it did not, as in the former cases of diabetes mellitus, already noticed, retard the action of the iodic acid much beyond the period observed in operating with a healthy specimen.

Dr. Willis remarks that " ureous urine has been observed to alternate with other morbid states of the same fluid, with the albuminous and saccharine particularly, and also with that in which the phosphatic salts are copiously elaborated. I believe it (he says) to be the common precursor, as recent inquiries have shown it to be the general attendant, of the mellitic diabetes, as well as the state into which that formidable disease passes, under the influence of treatment of a certain kind." We perfectly concur with these views, and have no doubt that our patient's disease would soon be converted into a confirmed diabetes mellitus, were he to live almost solely on vegetable food. There seems to be, therefore, a very faint line of separation between these two diseases; indeed the facts connected with their history seem rather to prove that they are only modifications of one another, and that the same morbid function which generates sugar in excess, has a similar effect in causing an excessive secretion of urea. The ureous diabetes, however, is a much less formidable form of the disease than the saccharine, and we think it is highly probable that its fatal or injurious effects might, for a long period, be protracted, by a careful attention to the diet and regimen, so as to prevent it from assuming the mellitic character. The history of the foregoing case proves decidedly that a diet composed chiefly of vegetable substances would have rendered it one of a decided mellitic character, and proves also the species of aliment is of more importance in the treatment than medicine, for the same formulæ was employed during this period. We have not a sufficiently extensive series of facts to support the opinion that ureous

urine generally precedes the diabetic form ; but it is a subject well worthy of investigation by experiment and observation, for if such were the case, diabetes mellitus might often be rendered a less formidable disease than it is at present.

ON THE

DISEASES OF CHILDREN.

By Dr. Joseph Merdes,
Physician to the Casa Pia.

THE diseases of children treated by Dr. Merdes belong chiefly to the period between the cutting of the teeth and puberty. No children are received into the Casa Pia before they have cut their teeth ; and among 1290 there are barely 400 who have attained puberty.

State of the sick ward from Jan. 1, 1837, to the end of the year.

Remaining from the previous year 50, admissions 440, discharged 465, remained 8, died 17 ; mortality 1 in 28.

In the sick ward of the orphans, remained from the previous year 15, admissions 213, discharged 201, remained 14, died 13 ; mortality 1 in 17.

The most frequent diseases were, bronchitis epidemica (influenza) 55, measles 180, scrofula, scrofulous ophthalmia, &c. 50, diseases of the skin, 120.

Phthisis caused a third of the deaths ; four cases of meningitis also terminated fatally ; three children died of scrofulous caries.

REMARKS. -- Scrofula demands the greatest attention. It is most frequent and most violent in girls ; but with proper attention to health it is curable, and not infectious. In the present situation of the Casa Pia it has become more frequent and worse than in the former one, because the present one is cold and damp ; damp cold favours scrofula, which is, consequently, common in those countries where such an atmosphere predominates. Children who are transplanted to a colder climate, as from India to England, or the Brazils to France, often become scrofulous.

Another cause of scrofula, first pointed out by Baudelocque*, is bad air, poor in oxygen, and overstocked with carbonic acid, which checks the formation of blood, and makes it imperfect. In the Casa Pia, where from want of room the children are crowded together in long and narrow bed-rooms, which in the long winter nights are almost hermetically closed, this cause is present in the most intense degree, and has an impor-

* The German translator puts a (?) to the assertion that this fact was first pointed out by Baudelocque.—*Translator's Note.*

tant share in the frequency of scrofula in the institution. As to remedies, Dr. Merdes remarks that the most celebrated antiscrofulous medicines, iodine not excepted, are of weak and doubtful effect, when, as in the Casa Pia, the conditions requisite to health are wanting.

The chief cause of mortality among the children is phthisis scrofulosa, which, as dissections show, commonly begins in the bronchial glands, which are usually found much swelled, and changed into tuberculous masses. Several die every year of meningitis and encephalitis, which are so common and severe among children. Therapeutic results by no means correspond to the improved view of the essence of those diseases which has been attained in our day. White and Fothergill considered acute meningitis as incurable ; and, according to Dr. Merdes' experience, the physician must necessarily lose two-thirds of such cases. Many children are carried off every year in the Casa Pia by stomatitis gangrenosa (stomacace maligna) ; but, from the greater salubrity of the place, it is not so common as formerly. —*Zeitschrift für die gesammte Medicin*, from the *Jornal da Sociedade das Sciencias Medicas de Lisboa.*

CASE OF

ABSCESS OF THE KIDNEY

MAKING ITS WAY THROUGH THE LIVER AND THE LUNG.

By Dr. Sporer.

P. B. æt. 19 years, a tailor, was attacked, without any evident cause, with pain in the lumbar region, accompanied by shivering, and followed by increased heat. On the 13th of February, the fifteenth day of his illness, he came to the hospital in the following state : — He had a dry cough, anorexia, heat of the skin, and thirst ; his tongue was covered with a yellow coat, and was dry at the tip ; his skin was pale, hot, and dry ; his pulse 90, rather tense ; his stools natural, and his urine highly coloured and heating. On lying on his back he felt a sensation of tension, and of an uncomfortable pressure ; when on his right side he complained of a dull pain in his right hypochondrium, and his cough became more frequent. His physician, believing he had rheumatism and gastro-catarrhal fever, prescribed nitre and tartarized antimony.

On the 15th and 16th his cough was more frequent ; his pulse 100. On the 17th he had severe pain in inspiration at the inferior angle of the right scapula ; he was ordered to be cupped there, and to take calomel with other mild medicines. On the 18th he had constant fever, and the pain was more severe in the hypochondrium and in

right lumbar region. The application of a blister was followed by a slight improvement ; the pain became less, the expectoration easier, and the cough less frequent ; the skin was burning hot and dry ; the urine scanty. On coughing forcibly, or taking a deep inspiration, a gurgling sound was heard, extending from the inferior angle of the right scapula to the hypochondrium of the same side. He was now also becoming rapidly and generally dropsical.

On the 27th the patient expectorated at short intervals, and after some severe paroxysms of coughing, nearly a kilogramme and a half of genuine, thick, greenish-grey pus, and immediately after he had an abundant perspiration. For two days after this he seemed rather better, but then he became much weaker, and he died exhausted, and with great difficulty of breathing, on the 4th of March.

At the examination, thirty hours after death, the pleuræ, heart, pericardium, left lung, and upper lobe of the right lung, were found healthy. The lower lobe of the right lung was adherent to the costal pleura at the back, and to the pleura covering the diaphragm. On endeavouring to detach it at the latter part, a rent was made, which permitted the escape of a little pus. On opening the abdomen to raise the part of the diaphragm which was adherent to the lung, the right lobe of the liver was also found closely adherent to the under surface of the diaphragm, and lower down, to the transverse colon, and by plastic exudations extending along the ascending colon to the right kidney, with which it formed one entire mass. The right kidney, enveloped, as it were, in a gelatinous mass, adhered to the vertebral column and to the ribs by means of a fleshy substance, and resembled, in some measure, a membranous bladder of the size of a large fist, which was filled by well-formed yellow pus. It was only at that part of the kidney which lay by the sides of the bodies of the vertebræ that any trace of cortical substance could be discerned. The left kidney, the left lobe of the liver, the gall bladder, the pancreas, the spleen, and the intestines, with the exception of the ascending and transverse colon, were in a normal condition.

It was evident that this disease had commenced by an inflammation of the right kidney ; that then suppuration took place, and extended along the ascending colon to the liver, and made its way through the diaphragm to the lower lobe of the right lung. The pus, therefore, had ascended, contrary to all physical laws, into the bronchial tubes, from which it was discharged by expectoration.— *Fricke und Oppenheim's Zeitschrift*, and *Gazette Medicale*, Aug. 8, 1840.

FORTY-TWO MUSCLES, TENDONS, AND LIGAMENTS,

PERFORMED ON THE SAME DAY IN THE SAME INDIVIDUAL,

By M. JULES GUERIN.

I HAVE the honour to communicate to the Academy (of Sciences of Paris) an account of an operation, which, by its character of generality, and by its immediate results, seems to me fitted to determine in a definite manner the value of a principle which I have endeavoured to establish in my memoir on subcutaneous wounds ; namely, that wounds made under the skin, and kept from the contact of the air, are secure from all suppurative inflammation.

On the 25th of this month, at 5 in the evening, I performed on a young man aged 22, the subcutaneous section of forty-two muscles, tendons, and ligaments, consecutively, to remedy a series of articular deformities caused by the active retraction of those muscles and ligaments. This series of operations required twenty-eight openings in the skin. The following are the muscles, tendons, and ligaments, that were divided :—

In the trunk—The pectoralis major.

At each elbow—The biceps, the pronator teres, the flexor sublimis, the palmaris longus.

In each fore-arm—the tendon of the flexor carpi ulnaris, those of the palmaris longus and brevis, that of the abductor pollicis.

At each knee—the sartorius, the biceps, the semi-membranosus, the semi-tendinosus, fascia lata, external lateral ligament.

At each foot—the tendo achillis, the tibialis anticus, the extensor communis, the extensor longus pollicis, the peroneus longus.

The following were the immediate results of the operations : the patient had felt but slight pain and fatigue ; he made no complaint whilst they were being performed, and they occupied an hour. An hour after he was in a calm sleep. The night and the day following were passed tranquilly. No inflammation supervened ; and on the third day the twenty-eight wounds were completely cicatrized. To-day, the fifth after the operations, the divided parts of the skin have had all their dressings removed, and the traces of the cicatrices are scarcely discernible. – *Gazette Medicale*, Sept. 5, 1840.

METHOD OF RESOLVING *ENGORGEMENTS* OF THE SPLEEN,

By M. VOISIN, of Limoges.

HAVING learned from the *Gazette Médicale* the attempts which have been made by several of its contributors to resolve the swelling of the spleen which follows ague, I have to propose a very simple remedy, by means of which I have not only cured eight or ten of these swellings, but also the ascites and straw-coloured complexion which often follows them. In three or four of these cases, the diseased organ occupied about two-thirds of the capacity of the left half of the abdomen. This remedy, which I do not call a new one, is merely an emplastrum Vigo cum mercurio,* with which 120 or 160 grains of sulphate of quinine are incorporated, and which is placed permanently on the splenic region. It must be renewed when the substances which compose it are exhausted, that is to say every forty or fifty days.

The following are the advantages of this remedy : —

1. It spares the patient the unpleasantness of taking sulphate of quinine by the mouth.

2. There is absorption, and consequently continuous action of the remedy.

3. This absorption and action take place in the very neighbourhood of the diseased organ.

4. In consequence of these effects continuing, the paroxysms do not return.

I have always found this treatment sufficient, without any other. What is its mean duration ? It would be difficult to estimate it from so limited a number of facts. The length of the treatment varies according to the greater or less swelling of the spleen, the age of the patient, and the absorbing power of his skin ; but two or three months are generally sufficient.

I will not quit this subject without mentioning that when taken *in the dose of sulphate of quinine*, the deuto-sulphate of iron is equally efficacious in ordinary intermittents. My underlining some of the previous words was intended to mark the error of certain pharmacologists, who, from erroneously dreading the energy of this remedy, prescribe it in insignificant doses.—*Gazette Médicale*, September 12, 1840.

* The " emplâtre mercuriel," or " emplâtre de Vigo cum mercurio" of the French Codex, is made of common plaster, bees' wax, rosin, ammoniacum, bdellium, olibanum, myrrh, saffron, mercury, turpentine, liquid storax, and volatile oil of lavender.—*Translator's Note.*

CASE OF VARICOSE ANEURISM TERMINATING FATALLY.

A PEASANT, aged 40, was admitted into hospital on the 9th of December, with a varicose aneurism at the bend of the left arm, which had appeared a few days after vene-section. A compressive bandage was applied for twenty-two days round the whole arm without advantage. On the first of January the brachial artery was tied according to Anel's method, and the operation was followed by the ordinary symptoms until the fifth day. At this period gastric symptoms set in; and the arm swelled to such a degree, that the aneurismal tumor, which was as large as a hen's egg, could no longer be distinguished. The wound began to suppurate copiously; and an obstinate diarrhœa terminated the sufferings of the patient on the 21st of January.

Dissection.—The brain, lungs, and intestines, showed traces of inflammation and accumulation of purulent mucus. The tied artery had suppurated, both above and below the ligature. The coagulum was of a conic shape; and close to it, as is usual in such cases, lay the sac of the aneurism. When opened, it displayed a double cavity, which appeared to have been formed at the expense of the cellular substance situated between the artery and the vein.—*Zeitschrift für die gesammte Medicin,* from the *Jornal da Sociedade das Sciencias medicas de Lisboa.*

BOTH TO BLAME.

'Tis a pleasant and witty saying that Plutarch says Democritus was wont to have, viz. " that if the body and soul were to sue one another for damages, 'twould be a doubtful question whether the landlord or the guest were most faulty."

And indeed we seldom find a just moderation between 'em; for if we are too intent upon strengthening the body, by cramming that we humble the soul to the ground; and if, on the other hand, we bend all our force upon the improvement and ornaments of the mind, the body moulders and decays. *Ramazzini.* London translation of 1705.

BRITISH MEDICAL ASSOCIATION.

THE General Meeting of this Association took place at Exeter Hall on the 8th inst. We regret that, owing to the ticket sent to us having reached us too late, we were unable to send a reporter of our own, but we subjoin the account of the meeting which appeared in the Times of next day.

Last night a crowded meeting of the members of the medical profession took place in the director's room, in Exeter-hall, Dr Webster, the president, in the chair, who explained to the meeting the objects which the Medical Reform Association had in view, and stated the objections with which the medical bills of Messrs. Warburton and Hawes were fraught. The heads of the bill which the Reform Medical Council deemed the most salutary to the public, and the most satisfactory to the profession, are—1. That all the legally qualified members of the medical profession be united into one body, to be named the British Faculty of Medicine. 2. That this faculty should have the power to elect by ballot a governing body, to be named the General Medical Senate, consisting of a senate in London, Edinburgh, and Dublin, to be elected by the respective members of the faculty in each country. 3. That these senates should be subject to the same regulations, and that their members, either in whole or in part, should assemble at fixed times to frame laws for the protection of the faculty. 4. That this general senate should alone have power to frame laws for the regulation of the faculty, for defending the rights and privileges of the members, for superintending the medical police of the country, and for advising Her Majesty's Government on all subjects connected with the public health. 5. That the members of the present existing corporations be requested to take part in the formation of the first medical senate. 6. That all future candidates for medical practice be examined by a board elected as the General Medical Senate shall suggest. 7. That an uniform high educational qualification be exacted from each candidate, to be tested by public examination. 8. That all candidates admitted shall receive the same title, enjoy equal rights and privileges, and alone have the power of exercising the healing art in the British empire, subject to certain limitations. 9. That no medical practitioner be permitted to sell drugs, or to compound any other than his own prescriptions, except in rural districts. 10. That those practitioners who act as general practitioners shall be allowed to charge for their attendance, in addition to the cost of the medicines. 11. That all chemists and druggists, compounders or sellers of medicines (henceforward to be styled apothecaries), shall undergo an examination before a board of the General Senate, and be licensed by that body. 12. That a continuous register be kept of those now practising, or hereafter to practise, the healing art; as also of chymists, druggists, compounder and sellers of medicines; and that such registers shall be deemed sufficient evidence of qualification. The secretary read the report of the year, when the meeting adjourned.

OPERATION FOR OVARIAN DROPSY.

To the Editor of the Medical Gazette.

Sir,

Mr. Liston requests me to state, with reference to the case of ovarian cyst published in the last number, " that he fully and earnestly dissuaded the patient against submitting to the extirpation of the cyst."

I am, sir,

Your obedient servant,

B. Phillips.

Wimpole Street, Oct. 12, 1840.

NEW TROCAR.

To the Editor of the Medical Gazette.

Sir,

The number of the Medico-Chirurgical Review, just published, contains an extract from your journal relative to an instrument I proposed to the pupils of Mercer's Hospital, to supersede the present trocar and canula. The writer of the article in the Review will find, on referring to Sir Astley Cooper's lectures on tapping, that the trocar and canula are not such eligible instruments as he supposes. Any contrivance, whereby the apparatus can be rendered more convenient and easily kept in repair, and which will attain the twofold object of dispensing with the edged canula (which wounded the mesentery, and caused death, in one of the cases described by Sir A. Cooper) and of preventing a speculative thrust where the fluid is deeply seated in encysted dropsy, is an improvement on existing practice. At the same time, it was rather my intention to direct the attention of ingenious instrument-makers to the subject, than to propose a plan myself.— I remain, sir,

Your obedient servant,

Charles Lendrick.

Dublin, October 3rd, 1840.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE V.

Different modes of dying. Pathology of sudden death. Death by anæmia, its course, phænomena, and anatomical characters. Death by asthenia, its course, phænomena, and anatomical characters. Syncope. Death by inanition. Death by apnœa : Death by coma : their course, and phænomena, and the anatomical characters common to both. Application of the principles obtained from the investigation of the phænomena of sudden death, in elucidating the symptoms and tendencies of disease.

I PROPOSE to devote the present lecture to the following inquiry :—wherefore it is, and how it is, that some of the corporeal changes which we have been considering, or the diseased conditions connected with those changes, come to be incompatible with the farther continuance of life ? how is it that they put an end to the working of the living animal machine ? why the machine should not continue to work, though, perhaps, imperfectly, *notwithstanding* such changes ?

When our watches stop, we take them to a watchmaker to ascertain why they have stopped. The watchmaker knows that there are various ways in which the movements of the instrument may have been arrested. The main spring may have broken : or the little chain that connects the barrel and the fusee may have snapped : or the teeth of some of the wheels may have become inextricably entangled : or the watch may have

ceased to go (as the saying is) simply because it has not been wound up. Now the examination which the watchmaker undertakes in respect to the watch, I am desirous of making in respect to the human body. I am going to inquire into the several processes and modes of dying—the steps, or ways, by which the vital functions of the body are extinguished. A very little experience in the sick chamber, or in the wards of a hospital, will suffice to teach you that, although all men must die, all do not die in the same manner. In one instance the thread of existence is suddenly snapped ; the passage from life, and apparent health perhaps, to the condition of a corpse, is made in a moment : in another the process of dissolution is slow and tedious, and we scarcely know the precise instant in which the solemn change is completed. One man retains possession of his intellect up to his latest breath : another lies unconscious, and insensible to all outward impressions, for hours or days before the struggle is over.

We seek to ascertain the laws and mechanism of these mysterious differences.

The inquiry is not one of merely curious interest, but has a direct bearing upon the proper treatment of disease. It will teach us what we have to guard against, what we must strive to avert, in different cases. In speaking of particular diseases, I shall constantly refer to the facts and reasonings which I am now about to lay before you.

Conditions of life.—In pursuing this inquiry, we need not go into any deep physiological disquisition respecting the conditions that are essential to life. It is sufficient for our purpose to remark that life is inseparably connected with the continued circulation of the blood. So long as the circulation goes on, life, organic life at least, remains. When the blood no longer circulates, life is presently extinct : and our investigation of the different modes of dying resolves itself into an investigation of the

L

different ways in which the circulation of the blood may be brought to a stand.

Observe the ample provision that is made, in the construction of the body, for carrying on and maintaining this essential function. First, there is an extensive hydraulic apparatus distributed throughout the frame, and consisting of the heart and other blood-vessels. Next, there is a large pneumatic machine, forming a considerable part of the whole body, and composed of the lungs, and the case in which they are lodged. Lastly, the power by which this machine is to be worked and regulated is vested in the nervous system. Each of these systems must continue in action, or the circulation will stop, and life will come to an end. The functions they respectively perform are, consequently, called vital functions: and their main organs—the heart, the lungs, the brain (by which I understand the intercranial nervous mass)—are denominated vital organs. The functions of any one of the three being arrested, the functions of the other two are also speedily extinguished. But the phaenomena of dying vary remarkably according as the interruption begins in the one or the other organ. Hence Bichat, who, in his *Recherches sur la vie et la mort*, laid the foundation of the distinctions I am about to describe, spoke of death beginning at the *head*, death beginning at the *heart*, and death beginning at the *lungs*. This nomenclature is, however, unsatisfactory and insufficient, as you will presently perceive.

That the heart may continue to propel the current of the blood, two things are necessary: first, a certain power or faculty of contraction; and, secondly, a sufficient quantity of blood in its chambers, to be moved, and also to stimulate them to contract. If this, the proper stimulus to the internal surfaces of the heart, be withheld, or much deficient, it will soon cease to beat. There are plainly, therefore, two ways in which death might be said to begin at the heart; and these require to be distinguished.

The respiration is entirely subservient to the circulation of the blood. The two organs, the heart and lungs, respond intimately to each other. The whole of the blood is sent by the right heart to the lungs, simply that it may there be submitted to the chemical action of the atmosphere. The respiratory apparatus is added to the body for the sole purpose of thus repeatedly ventilating the blood.

To this purpose also (setting aside all accidental impediments) two things are requisite: first, circumfused air to enter and depart at short intervals; and, secondly, alternating movements of the chest to cause its entrance and exit.

Now these movements, although they admit of being regulated by the will, are essentially involuntary. The ordinary acts of respiration depend upon a certain condition of the medulla oblongata. If this condition fails, the mechanical part of the respiratory process, and, consequently, the chemical part also, ceases.

The respiration hangs, therefore, directly upon the nervous system.

On the other hand, the action of the heart is not directly or necessarily dependent upon any constant nervous influence conveyed to it. The circulation goes on in an acephalous fœtus; it may be kept up, by maintaining artificial respiration, in a decapitated animal: nay, even when both brain and spinal cord have been abstracted from the body.

But though the nervous influence is not necessary to the movements of the heart—farther than as it is necessary to the respiration, and to the introduction of nutriment—it has been clearly ascertained that very sudden and extensive injury or shock to the nervous system may instantly paralyse the heart, and so stop its action.

There are certain states, then, of the brain and nerves, which, without directly affecting the heart, bring the motions of respiration to a pause: and there are certain states of the brain and nerves which act directly on the heart and arrest its play. That is, there are two different ways in which death might be said to begin at the head.

Hence, I say, the nomenclature employed by Bichat is defective and inaccurate.

Pathology of sudden death.—In order to see clearly the steps by which the circulation, and with it life, finally terminates, in the various forms of dying, we must study the problem under its simplest forms. We must examine the cases in which the vital functions are, each in their turn, *suddenly* stopped, by some known cause, operating upon this or that vital organ. We must take advantage of the experiment (if I may so call it) which is performed before our eyes whenever a healthy man is cut off at once by external violence, or by poison, acting directly upon a particular organ or system of organs. The inquiry might be assisted, and, indeed, it has been mainly carried on, by experiments made upon living animals of a similar conformation with man. But the pathology of sudden death is happily now too well understood to require any farther recurrence to that painful mode of " interrogating nature."

Death, as it takes place in disease, is usually complicated. Many parts are affected, and different functions languish, and various disturbing causes are in operation, at the same time. Occasionally, however, the process of dissolution is as simple and obvious as in death produced by violence; and in

most cases some primary and predominant derangement may be traced of this or that vital function ; and a tendency is more or less clearly manifest to one or the other of the modes of dying, which we may now proceed to consider in succession.

Death by anæmia.—And first let us examine that form of death which is caused by a want of the due supply of blood to the heart. This is called, with much propriety, *death by anæmia.*

The best examples of death taking place in this way are those in which it is the consequence of sudden and profuse hæmorrhage. The circulation fails, not because the heart has lost its power of contraction, but because blood does not arrive in its chambers in sufficient quantity.

We assure ourselves of this in two ways. In the first place, when the body of an animal is examined immediately after death from sudden and copious loss of blood, the heart is not found dilated, and full of blood, as it would be if it had ceased to act from a want of power to contract upon its contents ; but it is found empty, or nearly so, and *contracted.* Secondly, this conclusion is confirmed by the reverse experiment : by the effect, I mean, of the *transfusion* of blood. It is a fact well ascertained, first by experiments made upon animals, and afterwards by most happy trials upon the human subject, that in cases of apparent death from violent hæmorrhage the suspended functions may be restored by conveying a timely supply of blood into the vessels of the seemingly dead animal from the veins of a living animal of the same species. Now it is quite clear that this introduction of fresh blood could be of no avail in a case where the heart was unable to act upon the blood which had reached it.

The phænomena which attend this mode of dying are paleness of the countenance and lips, cold sweats, dimness of vision, dilated pupils, vertigo, a slow and weak pulse, and speedy insensibility. With these symptoms are frequently conjoined nausea, and even vomiting, restlessness and tossing of the limbs, transient delirium : the breathing is irregular, sighing, and, at last, gasping ; and convulsions generally occur, and are once or twice repeated, before the scene closes.

It is thus that women often die, in whom " flooding " happens after childbirth. Sometimes the sudden bursting of an aneurism occasions this form of death. It is common on the field of battle, and in accidental injuries whereby large blood-vessels are wounded. Internal hæmorrhage, depending upon diseases to be hereafter described, may also prove fatal in the same manner.

Death by asthenia.—This, then, is one form of death beginning at the heart. Another form, the converse of this, but spoken of also as death beginning at the heart, is that in which there is no deficiency of the proper stimulus to the heart's action, but a total failure of contractile power in that organ. This is well denominated death by *asthenia.*

Death occurring in this way is not uncommon. The effects of some kinds of poison furnish a good illustration of it. There are certain substances which, applied to some part or other of the body, speedily extinguish life : and when, after their fatal operation, the thorax is opened, each chamber of the heart is found to be filled with its proper stimulus, upon which it has been unable to contract.

This was distinctly made out by Sir Benjamin Brodie, in his able and scientific investigation of the effects of different poisons. You may read with advantage his papers on this subject in the Philosophical Transactions for 1811 and 1812. He ascertained, upon examining the chest after death occasioned by the *upas antiar*, that the heart was not empty, but full, there being purple blood in its right, and scarlet blood in its left cavities. These are the anatomical characters of this kind of death ; and they prove that the action of the heart does not cease from a defect of stimulus, but from a loss of its contractile power.

Syncope.—The state of suspended animation common to both these forms of dying— (the ultimate external phænomena being nearly the same in each, and the result in each being the simple failure of the circulation)—is often expressed by the term *syncope.*

Besides the essential distinctions between them already mentioned, there is this farther point of difference. In death by anæmia, the suspension of the functions of the nervous system arises from a lack of the blood which should be sent to the brain from the *heart.* Hence the well-known effect of mere position. Syncope is sooner produced by venesection when the person bled is sitting up than when he is recumbent : and the first remedy for the fainting state is to lay the patient flat upon the ground, or even to place his head a little lower than the trunk of his body. In the one posture the current of the blood towards the head is impeded by the force of gravity ; in the other it is not. In sudden death by asthenia this order is reversed ; the *nervous system* is the part first affected, and through it, consecutively, the heart. This appears from the fact that sudden death by asthenia is sometimes produced by causes which we know to act primarily upon and through the nervous system ; by strong mental emotion—as intense grief, joy, terror. Cases of fatal concussion, where the brain is jarred by some bodily shock—and death occurring almost instantly from blows on the epigastrium—

are of this kind. Lightning and electricity
kill too, when they kill at all, in the same
way.   And we shall hereafter see that cer-
tain varieties of apoplexy, and several other
diseased conditions, destroy life by suddenly
arresting the contractile power of the heart.

When death by asthenia occurs more
slowly, from disease, the phænomena are
somewhat different.   The pulse becomes
very feeble and frequent, and the muscular
debility extreme ; but the senses are perfect,
the hearing is sometimes even painfully
acute, and the intellect remains clear to the
last.   The tendency to death of this form is
remarkably manifest in acute inflammation
of the peritoneum, in what is called malig-
nant cholera, and in cases of extensive
mortification.

Death by inanition.—Akin to this form of
dying is that in which the living powers are
slowly exhausted by lingering and wasting
disorders, as in many cases of phthisis, in
diabetes, and in dysentery ; or by hæmor-
rhages moderate in amount, but frequently
repeated ; or by any other long-continued
drain upon the system : the death is partly,
however, to be ascribed to a deficient supply
of the natural stimulus to the heart's action.
The type of these mixed modes of dying is
seen in death by *starvation*, which may be
considered intermediate between death by
anæmia and death by asthenia.   Death from
inanition can never be sudden.   The blood,
renewed no longer from without, and fed
only by absorption from the system itself,
diminishes gradually in quantity, while its
quality is probably deteriorated.   Gradually
also the contractile power of the heart, as
well as of the muscles generally, is weakened ;
and from these combined causes its move-
ments at length cease.   Accordingly after
death by starvation the heart is not found to
be so much contracted, nor so nearly
empty, as after death by sudden and copious
hæmorrhage.

Certain diseases of the throat or the œso-
phagus, prohibiting the introduction of food ;
of the stomach, preventing its retention ; of
the digestive organs generally, hindering its
assimilation, are fatal in this manner.

We have yet to consider how death is
produced by the suspension of the respira-
tory function—in other words, by a want of
the due arterialization of the blood.

There are two perfectly distinct modes in
which this cause of death may happen ; dis-
tinct, *i. e.* in regard to the steps of the pro-
cess, although identical in regard to the
ultimate result.

1. When the access of air to the lungs is
suddenly denied by some direct obstacle to
its entrance ;

2. When the muscular actions required for
breathing cease in consequence of *insensibi-
lity*, caused by disease or injury of the brain.

The first of these two forms of dying is
commonly called death by *asphyxia*. The
second is conveniently termed death by
coma.   Bichat spoke of them respectively
as death beginning at the lungs, and at the
head.

Death by apnœa.—It is of much impor-
tance to get rid, when we can, of improper
names.   They are very apt to warp our
notions concerning the real nature of the
things they are intended to express.   This
term *asphyxia*, which is in every body's
mouth, is very inappropriate, if we look to
its etymology, to the kind of death which it
has come to denote.   It signifies, you know,
literally, pulselessness, the want of pulse ;
and therefore it *might* express any kind of
death whatever ; or if applied to any parti-
cular *mode of dying*, it would seem to belong
to that we have just been considering,
namely, death beginning at the heart.   And
you will presently see that it is *peculiarly*
inapplicable to all those cases where death
results from the nonarterialization of the
venous blood.   Its current signification has,
I am afraid, been too long established by
custom, to allow of its being restored to its
proper meaning without much confusion.
But, at any rate, I can and shall avoid its
use, and adopt in preference the generic
term *apnœa* (privation of breath) as justly
expressive of the mode of death to which
the word asphyxia is commonly given by
authors.   The generic English term is
suffocation.

The entrance of air into the lungs may be
prevented in various ways : by stoppage of
the mouth and nostrils *(smothering)* : – by
submersion of the same inlets in some liquid
(drowning) ; or in gases which, though not in
themselves poisonous, contain no oxygen ;
such are hydrogen, and azote : by mechani-
cal obstruction of the larynx or trachea from
within, as by a morsel of food *(choaking)*,
or from without, as by the bowstring, *(stran-
gulation)*; both these varieties are included
in the term *throttling*) :—by forcible pres-
sure made at once upon the chest and abdo-
men, preventing all movement of the ribs
and of the diaphragm ; this happens some-
times to workmen employed in excavating,
who are buried, their heads excepted, by the
falling of a mass of earth ; it was near hap-
pening, Dr. Roget tells us, to an athletic
black man, of whose body a cast was at-
tempted to be taken by one operation, and
in one entire piece, as an academic model.
" As soon as the plaster began to set, he felt
on a sudden deprived of the power of respi-
ration, and to add to his misfortune, was cut
off from the means of expressing his distress.
His situation was just perceived in time to
save his life ;" in this way the victims of
Burke and Hare were stifled ; and the same
immoveable state of the lung-cases is some-

times produced in tetanus, or by the poisonous influence of strychnine, all the respiratory muscles being fixed in rigid spasm :— by paralysis of the same muscles, from injury or disease of the spinal cord above the origin of the nerves that give off the phrenic nerve, and therefore above the origin of the intercostal nerves also ; or from section of the phrenic and intercostal nerves :—lastly, by such breaches in the walls of the thorax as admit air freely to the surface of both lungs, and spoil the pneumatic machine, as a pair of bellows is spoiled when deprived of its valve. Of course the same consequences ensue when both pleuræ become filled with liquid of any kind.

Whenever the privation of air is sudden and complete, the following external phenomena present themselves :—Strong but vain contractions occur of all the muscles concerned in breathing, and struggling efforts to respire are made, prompted by that uneasy sensation which every one has experienced who has tried how long he can hold his breath, and which, when unappeased, soon rises to agony : this extreme distress is transient, being almost immediately succeeded by sensations, not unpleasant, of vertigo, and then by loss of consciousness, and convulsions : at length all effort ceases, a few irregular twitchings or tremors of the limbs alone perhaps remaining ; the muscles relax, and the sphincters yield : but still the movements of the heart, and even the pulse at the wrist, continue for a short time after all other signs of life are over ; there is no *asphyxia* (properly so called) till the very last.

During this process, which does not occupy more than two or three minutes, the face at first becomes flushed and turgid, then livid and purplish, the veins of the head and neck swell, and the eyeballs seem to protrude from their sockets ; at length the heart ceases to palpitate, and life is extinct.

The internal changes, which correspond with and cause these outward symptoms, have been carefully studied, and accurately, though slowly and lately, ascertained. They all proceed from the prevention of the chemical alteration naturally produced in the blood, in the capillary vessels of the lungs. The blood, continuing venous, passes at first in considerable quantity through the pulmonary veins, into the left side of the heart, and thence, through the arteries, to all parts of the body. This venous blood is, however, inadequate to sustain, or sufficiently excite, the functions of the parts it thus reaches. In the brain the effect of the unnatural circulation is felt at once; and shewn by the convulsions and insensibility that ensue. The motion of the blood in the pulmonary capillaries is also, from the first, impeded, and its current gradually retarded, until it stagnates altogether ; the lungs remaining full, the right chambers of the heart distended, and therefore less capable of contracting. Meanwhile the black blood, flowing more and more tardily and scantily into the left chambers, leads by its unnatural quality, as well as its deficient supply, to feeble contractions ; and this side of the heart is comparatively empty.

In this state, even after the heart has ceased to beat, but not *long* after, if the cause which has excluded the air be withdrawn, and fresh air readmitted—in other words, if artificial respiration be instituted— the blood in the pulmonary capillaries undergoes the required change, becomes arterial, begins again to pass onwards, and by degrees the circulation is restored, and the patient saved.

In this mode of death, the circulation is first arrested, and death truly begins, *in the lungs.*

When the carcass of an animal that has thus perished of apnœa is immediately afterwards examined, (so speedy an inspection of the human body being, for obvious reasons, seldom practicable or proper), the left side of the heart is found to contain a small quantity of dark blood, while its right cavities are greatly distended, and the lungs, the cavæ, and the whole venous system, are gorged with blood of the same character. These are, in few words, the anatomical characters of sudden death by apnœa.

The pathology of this mode of dying has, I say, been thoroughly understood only of late. It will not be uninteresting, and may, I think, be useful, to trace briefly the successive steps by which the true explanation has been attained. Haller was of opinion that the quiescence of the lungs, consequent upon the cessation of the alternate movements of the thorax, formed a mechanical impediment to the further transit of blood through them ; and that death resulted from obstruction of the circulation *in the lungs.* He was partly right ; but he erred in supposing that the stream of blood was arrested absolutely, and at once, and by a mechanical obstacle. Apnœa, with all its peculiar phenomena, occurs, when atmospheric air is excluded, although the lungs continue to play ; as in persons who breathe azote or hydrogen gas. It was clearly shewn by Dr. Goodwyn, in his Essay upon the Connexion of Life with Respiration, that the unaerated blood passed through the lungs, and entered the left auricle and ventricle of the heart ; but he thought that it went no further. His notion was that arterial blood is the only stimulus which can excite the contraction of the left cavities of the heart, and that when venous blood arrives in them, the organ becomes motionless ; and no blood being sent to the brain, the person dies. Had this theory been true, the left chambers would be found full of

blood after death (which they are not), and the mode of dying would not have differed essentially from that which we have already considered as death by asthenia. The well-devised experiments of Bichat carried the investigation a step farther, and proved that the unaerated blood not only reached the heart, but was propelled by the contractions of that organ to every part of the body, through the arteries. Having applied a ligature upon the trachea of a living animal, he made a small opening in one of its carotid arteries. Presently the slender stream of blood that issued began to lose its florid tint, and to assume the dark colour of venous blood, but *it continued to flow*, and the afflux of this dark blood upon the brain was marked by convulsions and insensibility. Bichat conceived, therefore, the erroneous belief that the blood underwent *no* obstruction in its passage through the lungs, but that, remaining unpurified and venous, it acted *as a poison* upon every part to which it was carried by the arteries—first upon the nervous system, and ultimately (passing through the coronary arteries) upon the muscular substance of the heart itself. There are, however, two well-known facts, which upon this theory would be inexplicable—the comparative emptiness of the left chambers of the heart, and the restoration of the suspended functions by the timely performance of artificial respiration. The air could never reach and revivify or depurate the venous blood, stagnating in the capillaries of the heart. It was reserved for Dr. Kay to correct the unsound parts of Bichat's doctrine, and to shew that the blood begins to stagnate in the capillaries of the lungs, in consequence of its failing to undergo the change from venous to arterial ; and that the movements of the left heart are brought to an end, principally by the deficient supply of blood from the lungs. His experiments tend moreover to prove that venous blood circulating through the arteries has no directly poisonous operation, but is capable, though much less effectually than arterial blood, to support in some degree the irritability of the muscles. A muscle will continue to contract longer when supplied with venous blood by its arteries, than when supplied with no blood at all. Doubtless, in death by apnœa, the movements of the heart are weakened, partly in consequence of the imperfect stimulus afforded by the venous blood that penetrates its substance ; but the main cause of the failure of the circulation is the difficulty with which the nonarterialized blood finds its way through the capillaries of the lungs. This theory is consistent with all the phenomena observed. For a detailed account of the experiments and reasonings upon which Dr. Kay's conclusions are

founded, I must refer you to his work on Asphyxia.

Sudden death by apnœa is not very often witnessed as the result of disease. It sometimes is caused by a spasmodic closure of the rima glottidis. It is no uncommon consequence of accidents, in which the upper cervical vertebræ are broken or displaced. I have seen several instances of death rapidly produced, with all the symptoms of sudden suffocation, generally in intoxicated persons, in whom the chink of the glottis has been found closely plugged by a fragment of meat, which " had gone the wrong way."

But there are numerous forms of more chronic disease, in which the tendency to death by apnœa is plainly discernible, sometimes for a long while before their fatal termination arrives. And the phenomena are similar in character to those which are noticed when the struggle is short. We hear the patients complain of the " want of breath ;" we see how they labour to satisfy this want, when it becomes urgent, by the elevated shoulders, the dilating nostrils, the energetic action of all the muscles that are auxiliary to the respiration ; we perceive by the dusky and loaded countenance, the livid lips and ears, and eyelids, that the blood is but imperfectly arterialized. The diminished capability of such blood to support the functions of the brain is made evident by the vertiginous sensations, and the delirious thoughts of the gasping sufferers ; and after death we find the same distension of the right chambers of the heart, while the left are nearly empty—the same gorged condition of the pulmonary arteries and venous system generally, which constitute the anatomical characters of this mode of dying. These appearances are even more constantly visible in the dead body, when apnœa has been gradually produced, than after sudden suffocation ; simply, I believe, because they are more *permanent*. After sudden death, however caused, the blood seldom coagulates ; and the venous turgescence consequent upon rapid apnœa, although great at first, has time to subside and disappear before the body is examined.

In protracted cases, death does not take place purely in the way of apnœa ; the heart is weakened, and the nervous influence impaired by the continued circulation of imperfectly arterialized blood ; but the symptoms belonging to apnœa are plainly predominant.

When (as is most common) the privation of air is incomplete, and a scanty and sufficient supply is admitted, morbid changes take place in the lungs themselves ; the air-tubes and cells become charged with serous fluid, which operates as an additional cause of suffocation. The same phenomenon is

observed when the par vagum is divided on both sides.

Death by apnœa in disease is extremely common. It may be produced by any thing which narrows the chink of the glottis, by warts that sometimes grow there, by œdema of the submucous tissue of the larynx, by inflammatory tumefaction of its lining membrane : it may result from the presence of what are called false membranes in the windpipe and bronchi, such as are formed in the croup : it may be the consequence of disease situate in the substance of the lungs themselves, rendering them incapable of receiving the requisite quantity of air ; of this we have examples in pneumonia, and in pulmonary apoplexy :—or it may proceed from disorders of the pulmonary mucous membrane, the air passages becoming blocked up with excessive and unnatural secretions, as in bronchitis. Phthisis is sometimes fatal in the way of apnœa ; more commonly it tends to death by asthenia. Diseases of the pleuræ attended with effusion, and causing pressure upon the lungs ; diseases of the heart and great thoracic blood vessels, affecting the quantity of blood in those organs ; even certain abdominal maladies, accompanied by swelling, and thrusting the diaphragm upwards—terminate by the same mode of dissolution.

Death by coma.—Death by *coma*, although common enough, and of much importance to be understood, need not detain us long. Certain morbid states of the brain (it is unnecessary at present to enquire into their nature and origin) produce stupor, more or less profound ; the sensibility to outward impressions is destroyed, sometimes wholly and at once, much oftener gradually ; the respiration becomes slow, irregular, stertorous ; all voluntary attention to the act of breathing is lost, but the instinctive motions continue ; the stimulus conveyed by the pulmonary branches of the eighth pair of nerves still excites, though perhaps imperfectly, the reflex power of the medulla oblongata, which sustains the involuntary movements of the thorax. At length this function fails also—the chest ceases to expand—the blood is no longer aerated—and thenceforwards precisely the same internal changes occur as in death by apnœa.

You will observe that the extinction of *organic* life takes place in exactly the same manner in both cases ; the difference between the two forms of dying being this—that in death by apnœa, the chemical functions of the lungs cease first, and then the circulation of venous blood through the arteries suspends the sensibility ; whereas, in death by coma, the sensibility ceases first, and in consequence of this the movements of the thorax, and the chemical functions of the lungs, cease also. So that the circulation of venous

blood through the arteries is in the one case the cause, and in the other the effect, of the cessation of *animal* life.

The causes that destroy the sensibility leave no constant or necessary traces of their operation. The essential anatomical characters of death by coma, and of death by apnœa, are therefore the same.

Death occurring in the way of coma has this peculiar kind of interest belonging to it, that it may sometimes be effectually obviated by a mechanical expedient. The circulation ceases because the actions of respiration cease—and the failure of the acts of respiration arises from a suspension of the nervous power. If it be merely a suspension—if the nervous functions are within the verge of recovery—organic life may be sustained by the performance of artificial respiration, until the insensibility has passed away ; and thus the danger to life, which depended on that insensible state, may be escaped.

Many years ago, in the course of those researches to which I have already referred, Sir Benjamin, then Mr. Brodie, was led to think that by continuing the respiration artificially in animals labouring under the influence of narcotic poisons, the heart might be kept in action until the stupefying but transitory effect of the poison upon the brain had gone off. This idea he soon brought to the test of experiment, and the result was such as to justify his ingenious reasoning. He inserted some woorara into a wound which he had made in a young cat. After a certain time the respiration had entirely ceased, and the animal *appeared to be dead*, but the *heart* could be *still felt beating*. The lungs were then artificially inflated about forty times in a minute. The heart continued to beat regularly. When the artificial breathing had been kept up for forty minutes, the pupils of the cat's eyes were observed to contract and dilate upon the increase or diminution of light, but the animal remained perfectly motionless and insensible. At the end of an hour and forty minutes there were slight involuntary contractions of the muscles, and every now and then there was an effort to breathe. At the end of another hour the animal, for the first time, showed some signs of sensibility when roused, and made spontaneous efforts to breathe twenty-two times in a minute. The artificial breathing was therefore now discontinued. She lay, as if in a state of profound sleep, for forty minutes longer, when she suddenly awoke, and began to walk about.

Sir Benjamin Brodie had indeed been anticipated in this happy proposition for recovering persons apparently dead after taking narcotic poison, after submersion, and the like,—although he does not seem to

have been aware of it. The experiment had once been tried before, and on the human subject, and with success, though not upon such scientific principles. The case is given by Mr. Whately, in the Medical Observations and Enquiries, vol. vi. A man who had swallowed an immense quantity of solid opium, and who seemed to be dead, was restored by the patient continuance, on the part of his medical attendants, in a process of artificial breathing.

It is seldom that we can hope for success from this expedient in the treatment of disease ; simply because, in most cases, the injury of the nervous system, which has produced the insensibility, is irretrievable.

In most forms of apoplexy, and of hydrocephalus, death occurs in the way of coma. Sometimes, however, as I mentioned before, the lesion of the nervous substance is so extensive and sudden, as to operate like a shock, and cause death by asthenia. The tendency to death by coma is also strongly pronounced in sundry affections of the brain, both acute and chronic. These will form subjects for our consideration hereafter.

The several modes of dying, then, in cases of sudden death, are clearly enough made out. Let me briefly sum up the conclusions at which we have arrived. Life cannot be maintained without the circulation of arterial blood : and whenever a person dies, he dies either because *no* blood circulates through his arteries, or because *venous* blood circulates through them.

When it comes to pass that no blood is circulated through the arteries, we say that death occurs in the way of syncope ; and this is of two kinds. In the one there is not blood enough received by the left side of the heart to stimulate its chambers to contract, or to be sent onwards by their contraction ; in the other, there may be blood enough, but the heart has not sufficient power to contract upon it.

Also there are two ways in which death may be brought about in consequence of the circulation of venous blood through the arteries. In one of these, the first step is the sudden shutting out of air from the lungs ; the blood which arrives in those organs is not aerated, or rendered arterial, but circulates again as venous blood, producing a failure of the animal functions, and weakening the muscles, till it finally stagnates in the capillaries of the lungs themselves. In the other, the animal functions are the first to suffer—insensibility occurs—the power which governs the actions of respiration is withheld—the breathing ceases —and organic life is extinguished as in the former case.

I trust you even already perceive that a right understanding of these matters is cal-

culated to throw both light and interest upon our study of the symptoms, and of the tendencies of disease. It will enable us to aim with more precision at fulfilling the indication so often inculcated by Cullen, of " obviating the tendency to death." In this sketch I have merely been able to hint at the important bearings of such views upon our practice. My attention was first called to them by the lectures of my respected instructor, Dr. Alison, who was accustomed to illustrate them by reference to the phenomena of one large class of disorders. All the modes of dying that I have described are apt to take place in *fevers*. Sometimes we have to combat the one, sometimes the other tendency. The disease often proves fatal in the way of coma ; this happens principally when the brain has been a good deal affected, when there has been much headache, delirium, and stupor : sometimes, when the lungs have been seriously implicated, life is extinguished in the way of suffocation or apnœa ; and occasionally fever seems to terminate fatally in the way of syncope, especially when the stress of the disorder has fallen upon the bowels, when there has been continued diarrhœa, and ulceration of the intestinal glands. Or if death does not occur precisely in these ways, at least it resembles more in different cases, sometimes one form of dying, sometimes another.

It is notorious that very different remedies, and even different plans of treatment, have been strongly recommended, in fever, by different practitioners. One probable reason of this is that one plan has been found the most proper to avert the fatal event in one form of the disease, and one in another. The tendency to a particular mode of death will prevail in, and characterize, a whole epidemic. We shall resume these considerations hereafter : in the meantime the facts we have been reviewing may teach us the danger of applying, with too much confidence, the experience we may have gained of one epidemic to the treatment of another ; and the risk we are sometimes liable to, of misjudging, and criticising unjustly, the practice recommended by other physicians, because it does not appear to accord with the results of our own observation.

EXPERIMENTS

ON THE MOTIONS AND SOUNDS OF THE HEART.

BY THE LONDON COMMITTEES OF THE BRITISH ASSOCIATION FOR 1838-39, AND 1839-40.

EXPERIMENTS FOR 1839-40.

Obs. IV.—27th. *Subject*—A stout ass three to four weeks old. Heart acted very

vigorously until weakened by hæmorrhage, and continued to beat with considerable energy for two hours, when it was extracted still contracting. *Phenomena*—Effects of various forms of pressure on the heart. Rhythm of cardiac and arterial pulses. Ventricular systole. Auricular ditto. Sound of auricular systole. Pulsation of cava. Auricular diastole. Spontaneous or incidental variations in cardiac sounds. Protrusion of septum into right ventricle in systole.

Section 1. — A stethoscope loaded with 2 lbs. weight of shot in a bag was placed on the heart before opening the pericardium (as in experiment 3 of last observation), and was raised at each systole with a sudden heave or jerk, and with much force, and subsided immediately on the supervention of diastole, causing a deep depression in the previously convex surface of the ventricle. This experiment was repeated towards the close of the observation, and after the heart had been exposed for an hour and a half, and with like results in all respects.

Section 2.—The pulse of the femoral artery being compared with that of the heart was found to follow the latter by a distinctly perceptible interval, but by one very minute.

Section 3.—To the eye the apex and fundus cordis approximated to each other in systole, and receded in diastole. The motions of those parts coincided, to a great extent, but not entirely, but rather as part of a series of concatenated movements, of which the former part was the profound undulation, hardening, and rounding of the fundus, and the latter part the hardening, shortening, and slight elevation of the apex; between those successive appearances no very distinct intervals; they passed into each other by an undulatory sort of motion commencing at the fundus, and passing with extreme rapidity along the ventricles to the apex.

Section 4.—Threads were passed through the appendices of the auricles, and, being held tense, so as to impede the auricular systole, were felt to be drawn downwards with much energy immediately before the systole of the ventricles, auricular contraction being completed while the ventricles were still developing their systole.

Section 5.—Towards the close of the first hour of observation, and while the heart in its different parts acted with much energy, the auricles were observed, for a time, to contract with a rhythm above double that of the ventricles (owing probably to the irritation excited by passing the needle and thread through the appendices, and pulling at them afterwards); and a sound, to us new, was detected, resembling very much, except in volume, the first or ventricular systolic sound, and accompanying the auricular systole. The sound was short, rapid, obtuse,

without any jerking motion, and coincident exactly with the auricular systole, and in number double, or rather more, the sound of the ventricular systole. This sound was found to attend the systole of the right auricle, as well as that of the left, at a time when the action of the latter was too feeble to give sound.

Section 6. — The large pectoral veins, especially the cava, were observed to pulsate with the auricular systole something as the arteries do with the ventricular, but comparatively very feebly : first came the diastole of the vein, and then the systole, and then the pause; and the former followed immediately on the auricular systole; and the latter on the diastole of the auricles, both in the inferior and superior cava : no other motion was noted in the veins.

Section 7.—The diastole of the auricles was a gradual swelling and enlargement of the visible parts of the cavity in all directions, requiring for its completion as much time as several systoles would do, and followed on the instant of the full distension of the appendices by systole of the whole heart—first in the auricles, and then instantly in the ventricles : during its diastole the auricle seemed to the eye to emerge, as it were, from the sinus venosus, and to swell out from a state of collapse, such as suction inwards towards the ventricle might cause, if any such force as suction existed in the heart.

Section 8.—In this, as in every observation, abnormal murmurs were observed at various moments, viz., immediately on the injection of the woorara, and at other times, but especially when pressure was made, whether intentionally or otherwise, over the orifices, external and internal, of the heart. Towards the close of the observation a loud musical sound was detected in the pulmonary artery, with the diastole. At various times, for short spaces, the second sound of the heart was indistinct, or absent, or masked by murmurs without obvious cause in most instances, other than abnormal modes of action from irritation, hæmorrhage, &c. and exclusive of known structural changes. The first or ventricular sound was often modified in various ways, and attended by murmurs, but never was wanting, so long as the heart acted with any energy. Towards the close, however, when the ventricular systole had become slow and gradual from quick and abrupt, the first sound was either very feeble or not distinguishable at all.

Section 9.—The pulmonary artery was cut open, after which the first sound was still heard, but rather obtuse. A finger was then passed into the right ventricle, and the septum was felt to project convexly into the cavity, and in each systolic effort to press against the finger.

Section 10.—Post-mortem. One valve of

the pulmonary orifice was found slightly in-
jured by a puncture made in the course of
experiments, in which the parietes cordis
were irritated to abnormal action by means
of a needle. Wherever the needle penetrated
into a cavity of the heart, there a clot was
to be found, or, at least, a coloured plug
of lymph in the internal opening.

Section 11.—Post-mortem. The ventri-
cles were found to be of the same dimensions
on careful examination.

Obs. V. and VI.—July 1st, 1840. In
two observations, one on a frog and a second
on a rabbit, the following results were ob-
tained :—

Rhythm.—The first contraction after the
pause or ventricular diastole was observed
in the vena cava, to which immediately suc-
ceeded contraction of the sinus, and after-
wards, immediately, of the appendix of the
auricles, to which latter immediately suc-
ceeded the ventricular systole ; and the dias-
tole or relaxation of each part succeeded in
like order, that of the vein first, then of the
auricle, (of which the appendix seemed later
in its diastole than the sinus or body), then
of the ventricles. Those motions were
slower much than in the human subject,
somewhere about 50 beats per minute. The
series of systoles above mentioned succeeded
each other so, that at a little distance they
appeared collectively like an undulation
commencing at the cava, rather than a series
of independent actions.

Systole of ventricle. — In diastole the
ventricle was round, full, protuberant, and
dark in colour, but on the supervention
of systole changed rapidly in shape and
colour, from purple becoming pale flesh-
colour, like veal, and from round and
broad becoming apparently narrow and
more conical and depressed, being obviously
lessened in all dimensions, but most strikingly
in the transverse.

The action of the heart lasted for an hour
or more with great regularity. The auricles
acted for some time longer than the ventricle,
especially the right auricle. Nearly but not
quite at the same instant of time with the
vein, the base and then the apex of the
auricle were seen to contract, after which
(but not so quickly as might have been
expected from other observations, owing
probably to delay in the establishment of
artificial breathing), the ventricles entered
into their systole, and the diastole followed in
like order : first the venous expansion, next
the base and appendix of the auricles, and
last of all the ventricle.

Section 2.—Towards the close of the ob-
servation the auricles acted much more
frequently than the ventricles, and especially
the right auricle. In the ventricular systole
the apex was thought to move slightly out-

wards and to the left, or away from the
septum or central axis of the heart.

Obs. VI.—In the rabbit the heart did not
beat at any time very vigorously or regularly,
and ceased altogether after 20 to 25 minutes,
although respiration was maintained by the
bellows with ease.

The rhythm.—Section 1.—The first mo-
tion after the pause or ventricular diastole
was observed in the base of the auricles, and
on the right side in the expansion of the
jugular and subclavian veins, which in the
rabbit, as Steno has observed, seems to
replace the superior cava : this vessel
whose dimensions were very large com-
pared with the heart, and which wound
round the root of the heart in its way to the
auricle from above downwards, and from left
to right, continued to pulsate for some time
after the ventricles had ceased, and even
after the adjoining auricle had been for some
minutes inert.

Obs. VII.—July 2d. A snake of good
size poisoned with prussic acid, so as to be
insensible. Heart beating very slowly and
rather irregularly at first, perhaps 15 to 20
beats per minute only.

Rhythm of motions.—After a long pause
first motion observed in sinus of auricle, and
then in appendix, being the auricular systole,
immediately after which the ventricular
systole, but with no complete interval be-
tween end of one and beginning of other
systole. After the systoles respectively came
the diastoles in like order, and then a long
pause, equal sometimes to three or four,
or more beats.

At each auricular systole a swelling ob-
served in the cava and pulmonary veins,
extending some way down from the heart.
This appearance resembled a wave of reflux
excited by the action of the auricle. It was
not observed in any part beyond a point of
the vessels on which pressure was made. In
the systole the ventricle shrunk concentrically,
being shorter and narrower, but also rounder
and more oval, than in diastole ; the ven-
tricle, which might be called bicornute,
being obtusely pointed at either extremity,
had either horn or extremity raised slightly
in systole, and depressed again as if by gra-
vitation in diastole. The cavities systolized
and diastolized still after the observation was
completed, or for more than an hour, and
more regularly than at first.

July 3d.—The ventricle ceased beating
after about 20 hours. The rhythm of the
motions of the heart as before. But the
reflux wave or diastole of the veins now less
distinct, owing probably to the emptiness of
the heart. And in lieu of the regurgitation
wave marked by a diastole, followed by a
systole, and then a pause in the veins, there
was observed an opposite order of the mo-

tions, viz. 1. Venous systole; 2. Venous diastole; 3. Then pause. Several times the motion of the veins was observed alone, and not preceded by auricular contraction or accompanied by it, as towards the close of other observations auricular contraction had often failed to excite, or be followed by ventricular systole.

OBS. VIII. — July 4th. *Subject* — A donkey nine months old, in good health; pulse being strong in the præcordia, about 70 or 80; operation of injection tedious, with considerable hæmorrhage; whole operation lasted half an hour, and heart acted for considerably more than an hour. When opened the heart was beating quickly (above 100) but regularly; second sound indistinct. *Phenomena*—Effects of pressure on the heart. Action of threaded auricles. No ventricular sound, and why. Manner of auricular diastole. Resistance to pencil in mitral orifices, and how caused. Pulsation of cava. Phenomena of ventricular systole. Mechanism of cardiac impulse. Valvular jerk over the mitral opening in systole, and modifications of first sound artificially produced hæmorrhage from left auricle. Relative sizes of ventricles.

Section 1.—The stethoscope, loaded with four to five pounds of shot, &c., and placed on the ventricles as before, was jerked up by each systole, and subsided and deeply indented the parietes in each diastole.

Section 2.—The callipers were applied as before, but with a tension much exceeding that formerly used, and with a similar but not equal result; the heart being considerably less vigorous, as well as the spring much stiffer. The action became much hurried under the pressure of the instrument, but the legs were pushed asunder with some force in systole, and a deep indentation was caused by them in the parietes in diastole, which did not wholly disappear sometimes in systole.

Section 3.—The tip of the appendix of the left auricle was threaded as before, and the auricle and ventricle acted nearly but not exactly in alternation, and the thread was felt to be forcibly drawn downwards at the moment of auricular dimpling and systole.

Section 4.—No auricular sound could be distinguished, apparently owing less to want of energy in the auricle than to the rapid beat of the heart, and sudden supervention of the ventricular systole before the completion of the auricular. The left appendix was repeatedly inverted with a pencil and with the finger, and on the instant of being let free recovered its shape and position, appearing to emerge with rapidity out of the auri-ventricular orifice and sinus, apparently owing to a continuous and copious influx of venous blood into the appendix, especially during the systole of the ventricles.

Section 5.—In experiments on the mitral valves, repetitions of former trials, and with

inverted auricles; some resistance, as of a hard edge, was repeatedly felt by the finger, and the pencil was pushed outwards with some force: but the edge felt was suspected to be the edge of the interior orifice. and not a valve. On the inner side, or that next the septum, the resistance in systole was more energetic than on the outer.

Section 6.—The thread that had been passed through the appendix was drawn upwards to check the systole during auscultation of the auricle, but the operation was difficultly performed, and, at all events, no perceptible difference resulted. The first cardiac sound appeared unchanged.

Section 7.—A slight motion of the cava was observed accompanying the auricular systole, viz. a diastole followed by a systole; both slight.

Section 8.—In systole the auricle became rounder. harder, tenser, and shorter. Both fundus and apex, but especially the latter, were elevated, and the apex seemed to turn slightly from left to right.

Section 9.—An eccentric impulse or abrupt push outwards was perceived on whatever side we touched, while the heart acted with any energy; and this push or impulse was most striking, though least powerful, just at the apex; on account, as it seemed, of its pointed form.

Section 10.—An undulatory sort of motion was perceived in systole, from fundus to apex along the parietes. In addition to the general eccentric impulse, there was observed over the orifices, arterial and auricular, a jerking motion not observed elsewhere; and this jerking was indistinct or null over the interior orifice in a subsequent experiment, in which the mitral valves were prevented from closing by a slender instrument something like scissars, the parts of which beyond the joint were introduced through the auricle without inverting it into the auri-ventricular opening, and while the blades were kept separate the first sound, as heard on the ventricles, was found to begin dull and obtuse, and an obtuse beginning, and a well defined beginning, were heard alternately, according as the blades were separated or brought together, and as consequently the valves were obstructed or left free.

Section 11.—The tip of the left auricle was snipt off, and hæmorrhage was excited, which was constant, but with slight jets at the systoles of the auricles.

OBS. IX. and X. — 7th. Operated on two rabbits; one a large vigorous domestic one, and the other a smaller wild one. Both stunned by a blow on the head. The larger one was violently convulsed before death, and when the chest was opened the heart was not beating, and the only result obtained was :—

Section 1.—Distinct beatings in the large

vein on the left side, which winds round the base of the heart to empty itself in the right auricle. The actions observed were a systole followed by a diastole, and then a short pause. There was no auricular systole; the venous beating continued for many minutes.

Section 2.—The second heart acted for some minutes with some energy, especially the right cavities. The left cavities were drained by hæmorrhage, owing to an accidental wound in the superior great vein in opening the thorax. For some minutes the rhythm of the action of the cavities went on normally : first, the very rapid and abrupt auricular systole, and then immediately the ventricular systole, more gradual and of longer duration, and then the pause.

Section 3.—When the left ventricle acted, the apex cordis seemed slightly deflected to the left in systole, dragging the apex of the right after it ; and when the right ventricle acted alone, no deflection to the left was observed.

Section 4.—For a considerable time after the cessation of the left side, the right cavities acted regularly ; but after five to ten minutes, the ventricle especially began to flag, and the auricle then acted frequently without any following ventricular systole. But on one occasion, without obvious cause, the auricle became sluggish, and even for a few moments motionless, while the ventricle acted by itself more than once.

Section 5.—In the systole the apex approached the base, and the opposite sides approached the septum cordis, and the whole organ became rounder and more globular. In one direction, viz. the vertical, the heart always, when acting with any energy, became larger, while every other diameter was diminished.

Section 6.—After cutting out the heart, and before cutting out, but after cessation of spontaneous motion, systole was easily excited by irritating with scissars, &c ; and after the left had nearly wholly ceased to answer stimuli, still the right ventricle contracted on the point of a scalpel being applied to the left ventricle.

Obs. XI. and XII.—11th. *Phenomena.* —Stroke and sound obtained as if from locomotive force in systole of ventricles. Rhythm of the heart's motions. Manner of auricular action. Same of the ventricular venous motions. Mechanism of the cardiac throb or impulse. Mode of hæmorrhage from a wounded auricle.

11th.—*Subjects.*—Two donkeys operated on. One about six weeks old, the other two and a half months. Both rather weak from fasting twenty-four hours, owing to being too young to eat or drink properly. Each heart ceased to beat after above half an hour. First animal had his forehead beaten in so as to stun him, and chest then

opened. Heart acted quickly and not very regularly. No distinct second sound. No auricular sound.

Section 1.—Before opening pericardium, a hard flat body, having a piece of lead weighing about a quarter of a pound fixed on it, was placed on the heart, and a stethoscope was held at a short distance over it, *i. e.* at a quarter or third of an inch ; and at each systole of the heart the lead rose up abruptly and struck the stethoscope with a tick audible at some yards distance, and receded with diastole to sometimes nearly half an inch, and again rose up and impinged in systole, and so on.

Section 2.—The pericardium was then opened, and the auricles and ventricles observed. No auricular sound could be detected. The auricles acted immediately before the ventricles, and after the pause or rest, and very abruptly and rapidly, though the heart acted rapidly, probably considerably above 100 per minute.

Section 3.—The auricles were observed to dimple and contract all round, from periphery to centre, as in former observations.

Section 4.—The changes in the ventricles were particularly plain and striking. The apex obviously moved slightly upwards and to the left, and was drawn towards the base in systole ; while the horizontal transverse diameter of the heart, as the animal lay on its right side, was diminished ; and the transverse vertical diameter, and that alone, was increased, owing to the heart becoming, from flattish inferiorly and superiorly, convex, and from in the centre compressed or depressed, strictly globular or protruding, so that the central longitudinal axis was elevated during systole, and lowered in diastole ; while in diastole the apex rather approached the sternum, from which it had receded in systole, owing to shortening of the organ.

Section 5.—The veins were observed ; and except perhaps a slight undulation downwards during auricular systole, evinced by a diastole followed by a systole, both very slight, nothing decided was observed. As in all former observations, the ventricles and auricles respectively acted together.

[To be continued.]

CASES AND OBSERVATIONS

ILLUSTRATIVE OF THE

MERCURIAL TREATMENT OF SOME FORMS OF INCIPIENT PHTHISIS PULMONALIS.

By William Munk, M.D.,
Physician to the Tower Hamlets Dispensary.

[Continued from p. 118.]

The close connection existing between irritation or inflammation in one

or other of the tissues of the lung, and tubercle as cause and effect, has been particularly dwelt upon by Andral *, who enumerates the following as the principal morbid alterations accompanying the development of tubercle :—first, hyperæmia of the bronchia of a certain size ; second, hyperæmia of the air cells and ultimate ramifications of the bronchia without obliteration of their cavities ; third, hyperæmia of the same parts with considerable thickening of their parietes, and obliteration of their cavities ; fourth, an effusion of blood into the tissue of the lung ; the blood thus effused coagulates, becomes a living part, and secretes tubercle†. In reference to these pathological conditions he states that, in certain cases, and those not the least numerous, *the morbid alterations of the lung were evidently prior to the formation of the tubercles, and contributed to produce them.* In the Clinique Médicale there is a passage explanatory, in some respects, of that just quoted. In it the author alludes to the influence of bronchial inflammation as giving rise to tubercle ; but the explanation will, *mutatis mutandis,* apply with equal force to the same pathological condition elsewhere situated. " What ought never to be lost sight of," says he, " is this—that, in order that inflammation of the mucous membranes of the air-passages shall be followed by the production of pulmonary tubercles, it is necessary to admit a predisposition. This being admitted, we can easily conceive how, in one individual, very slight bronchitis is sufficient to produce tubercles, whilst others do not become phthisical from the most severe and long-continued pulmonary catarrh." Sir James Clark also expresses his belief that inflammation in a tuberculous constitution may give rise to the deposition of tuberculous matter in place of coagulable lymph, which, in healthy subjects, is its natural product, and thus inflammation may be one of the immediate causes of tuberculous disease‡.

I have quoted these authorities at length, because I conceive that the recognition and just appreciation of the facts and opinions therein contained will

have a most important bearing upon practice, and because each day's experience leads me to the opinion that cases like to these are far more numerous than is now generally admitted. The existence, in one class of cases, of inflammation within the lung, to be succeeded by the deposition of tubercle as cause and effect, is widely different from those in which an inverse relation obtains—where tubercular matter is first laid down, and inflammation follows either as consequence or coincidence. The causes determining tuberculous disease towards the lung are, in these instances, widely different ; in one it is well known, and within the reach of medicine ; in the other it is unknown, and the means at our command are comparatively inoperative. One class of cases are curable, though, from circumstances, not always cured ; the other are incurable, as regards medicine, though nature's efforts are, in a few rare instances, more successful.

As inflammatory action is in these cases the distinguishing characteristic, and throughout performs so important a part, it is but natural that, to its consideration, much attention should be given, and that its removal should be held as a canon of the first importance in our treatment. Blood-letting, either general or ·local, counter-irritants, emetics, digitalis, &c., the means which experience testifies to have been the most efficient in the treatment of phthisis, act principally by the removal or diminution of inflammation, determination of blood, congestion, and the disordered movements in the system to which their existence gives rise. These measures are, however, rarely sufficient for the perfect cure of the pathological conditions above mentioned, more particularly of the variety termed scrofulous, or the modification impressed upon inflammation by its occurrence in a scrofulous constitution. Highly important as auxiliaries, they must in no case be neglected, but as controllers of the disordered action of the capillaries, which constitutes inflammation, they are, in the majority of instances, inoperative. A medicine was wanting more potent in its effects, one whose action was evidenced not so much upon the central organs of the circulation as are blood-letting and digitalis, but on the periphery of the system, the capillaries.

---

* Pathological Anatomy, translated by Drs. Townsend and West, vol. 2, p. 553.
† This opinion of the secretion of tubercle by the blood itself M. Andral has since eschewed.
‡ Op. citat. p. 46.

Iodine and its numerous preparations have been recommended to public confidence, as a medicine calculated in some degree to meet this want. The action of iodine is manifested principally as a stimulant of the capillaries; by giving tone to these vessels it expedites the circulation through them, obviates and removes congestion, and frees the secretions. It exercises little, if any control, upon the peculiar action, whatever it be, that constitutes inflammation; but after the removal of this state a degree of congestion commonly remains, and here iodine is most effectual. Reliance must not, therefore, be placed on iodine in the class of cases and stage above described, although it comes in, as we shall show, with excellent effects, at a somewhat later period of the treatment.*

It has, by abundant experience, satisfactorily been proved that in the treatment of common inflammation there are no means at our command which, in point of efficacy, will bear comparison with mercury. However much pathologists may differ as to the proximate cause of this state, or writers on the effects of medicines as to the mode of action of this mineral, they one and all agree in the truth of the above assertion. The knowledge of this fact suggested to the mind of Dr. O'Beirne the employment of mercury in scrofulous affections of the joints. He regarded the inflammatory action attending these cases as a point of primary importance, and to its immediate removal directed all his attention. The results of the practice he was thus led to adopt proved the correctness of his ideas, no less than the value of the measures upon which he relied, whilst the adaptation of a like practice to those forms of phthisis during the earlier periods, of which inflammatory action is the predominant and all-important local condition, led to scarcely less successful results in the hands of Drs. Graves, Stokes, and Corrigan.

Mercury has heretofore been frequently proposed by distinguished authorities as a remedy in consumptive cases. It has never, however, acquired any great celebrity in the treatment of this disease; the proposals and recommendations for its employment, whensoever or from whomsoever originating, appearing to have passed unheeded by the bulk of the profession, or if attended to and followed to have fallen short of the expectations which its too sanguine advocates had raised, and thus to have dropped again into disuse. Among those who have recommended mercury we may mention Dr. Rush, and other physicians, his contemporaries, in Philadelphia. A perusal of their writings will clearly substantiate the charge of what to us must appear indiscriminate practice—a fault less justly perhaps to be attributed to them than to the imperfect state of our science at that period. Upon no point in practical medicine were our predecessors more likely to run into error. The absence, until within a very short period, of any correct information as to the precise nature and production of tubercle, the limited period during which mercury is in truth available, and the difficulty which existed, previous to the introduction of the new methods of diagnosis, of distinguishing the proper cases and their stage, were circumstances which one and all tended to render somewhat indiscriminate the application of mercury. Here, as in all other instances of indiscriminate practice, the evil results must have far exceeded the beneficial. Under such circumstances it cannot be matter for wonder that careful practitioners should have opposed the practice, or that teachers should have laid it down to students as an axiom in practical medicine—that the employment of mercury in scrofulous disease, but especially in phthisis, was fraught with danger, and could be productive of no good.

The injurious effects now alluded to, as ensuing from the employment of mercury in phthisis, are less attributable to the existence of pulmonary disease than to that of general disordered action of the whole system, of which the former is the consequence, and a certain indication. Our best writers agree in the belief that the full action of mercury in the scrofulous cachexia is singularly injurious; that the depression which the medicine thus given

---

* There are peculiarities in the action of the analogous substance, bromine, which seem to point it out as peculiarly adapted to certain forms of scrofulous disease, especially phthisis. I am at this time making comparative trials with the bromide and iodide of potassium, the results of which, I hope, at a future period, to lay before the profession. Of its superiority in some forms of cardiac disease I am already pretty fully convinced.

produces is more effectual than any other in increasing the cachectic state, and, should tubercle exist, in hurrying it through its various changes. It has, moreover, been asserted, and probably with some justice, that the mercurial fever once excited has a great tendency to increase hectic, and even in cases where this last condition has never appeared to pass gradually into and terminate in it. Hence will appear the justice of the view entertained by Dr. Stokes, when he terms the remedy a two-edged sword, and expresses his conviction that its exhibition must not be lightly attempted.

In coming to a conclusion as to the employment of mercury in any particular case, we have to decide on the propriety of employing means which are calculated to remove local disease, but do so at the expense of, and with some detriment to, the general constitution. In a word, our conclusion hinges on this, whether the local or the general disease be at this time the most important. Dr. Stokes writes as follows[*]:—" As to the general employment of mercury in incipient phthisis, I am any thing but sanguine, yet that by its assistance in removing irritation from the mucous membrane and parenchyma we may occasionally arrest the development and progress of tubercle, seems more than probable, for there can be little doubt that in the scrofulous habit there is more danger from the persistence of irritation of the lung, than from the action of mercury on the system."

The existence, then, of such irritation or inflammation, whether membranous, parenchymatous, or, as is most frequently the case, the two combined, is that which calls for immediate attention to the lung, even at a temporary disregard of the constitution. Dr. Corrigan[†] says that the use of mecury is in removing that degree of low local inflammation, which, allowed to remain unchecked or improperly treated, would terminate in tubercular deposition and consequent phthisis. And Dr. Graves[‡] after mentioning those cases of consumption which arise gradually and insidiously, whose commencement it is

impossible accurately to determine, goes on to say, " the reason of this is because the tubercular affection of the lung is in such patients only of secondary importance, the disease which produced it having affected the whole system before the lung was contaminated. This happens in some, but in others an opposite train of phenomena is observed, and scrofulous inflammation commences in the lung before any general contamination of the system has taken place. It is in such cases, and such only, that mercury ought to be tried, and it will avail nothing except where the commencement of the scrofulous inflammation of the lung has arisen suddenly, and in consequence of the operation of some obvious cause, as catching cold, or the occurrence of hæmoptysis."

It may then, in general terms, be stated that the absence of pre-existing tubercular deposit from every organ of the body is the circumstance justifying our neglect of the contra-indication which scrofulous cachexia presents to the employment of mercury. The word pre-existing has been here introduced, because it seems likely from the physical signs that, in some cases terminating favourably, tubercular matter has been present in the lung before the mercurial treatment was commenced. In them, however, such deposit was trifling in amount, and secondary to, and dependent upon, the bronchial or parenchymatous inflammation, for the cure of which mercury had been employed.

An interesting and most important object of inquiry is, how far such tuberculization may proceed, and the case nevertheless be amenable to mercury. Facts are wanting to decide this point. In one of Dr. Stokes's favourable cases " the antero-superior portion of the left side sounded comparatively dull." In another " the right clavicle and scapular ridge sounded slightly, but decidedly dull." In one of my cases (No. IV.) there was slight dulness of the left scapular ridge; in another (No. VI.) the same phenomenon, in an exceedingly slight degree, was perceptible upon percussing the left scapular ridge, the clavicle, and the two superior ribs. I must, nevertheless, in the face of these cases, express my conviction that the presence of dulness diminishes greatly our chance of suc-

* Op. citat. p. 450.

† LONDON MEDICAL GAZETTE, 2d Series, vol. iv, p. 74.

‡ Loc. citat.

cess; and did the previous history and general symptoms leave me in much doubt as to the propriety of employing mercury in any particular case, the existence of a very moderate amount of dulness would induce me at once to omit its use. I agree, indeed, with Dr. Hughes, in thinking " that appreciable dulness on percussion is very far from being an early physical sign of phthisis, and that when it is clearly distinguishable below one or both clavicles, or in the acromial regions, the complaint has generally advanced too far to be effectively treated." It must, notwithstanding, be borne in mind that dulness on percussion may even in cases of undoubted phthisis arise from other causes than the deposition of tubercle, and may either spontaneously or from the effects of treatment be considerably diminished, and even altogether removed from certain portions of the lung. The cause of dulness in such cases is either inflammation or congestion, and it is to intercurrent attacks of this nature, and their subsequent removal, that we are to attribute the alteration of the phenomena above mentioned. Many writers are of opinion that the dulness occurring very early in consumptive cases is more owing to congestion or inflammation of the lung than to the presence of tubercle. That such is the correct explanation of the cases above referred to, where dulness has been recovered from, seems more than probable. Every one at least must admit that such an explanation is more consonant with our knowledge of the habitudes of tubercle, and the effects of medicine, than that which would attribute it to the absorption of tubercle itself. Admitting the occasional absorption of tubercular matter to be a well-established fact, it yet remains to be proved that such a process is favoured by the action of mercury upon the system. Without, however, denying that such may be the case, and allowing that analogy is in favour of the supposition, it must be confessed that the present state of our science by no means warrants us in receiving this effect of mercury as more than probable.

The period, however, which may elapse between the commencement of the indisposition and the deposit of such a quantity of tubercle as to produce dulness, varies much in different cases. It may be stated, perhaps, as ranging between three weeks and three months. I have known the lung so far solidified within the former period as to put the use of mercury quite out of question. The attack supervened in this instance upon measles. In the course of three weeks the superior portions of each lung gave a perfectly dead sound upon percussion, and there was an entire absence of respiratory murmur in the same parts. The patient, æt. 18, died within nine weeks from the commencement of his illness, and upon examination cavities were found in the apex of each lung; the surrounding parts being completely solidified. That the condition above described may continue for eleven weeks, and so small an amount of tubercle be deposited as but slightly to impair the sonoriety of the lung, is proved by the case of Thomas Smith (No. VI.) below detailed. My experience has not been sufficiently extensive to enable me to say whether or not it may last longer without giving rise to marked dulness. Two cases I have witnessed, the histories of which were so perfect as to leave little or no doubt as to their nature, where a period little exceeding three months sufficed to induce well-marked dulness, and render the use of mercury inadmissible. One of these cases came under my observation fourteen, the other fifteen weeks from the commencement of the illness. That the usual course and tendency of scrofulous bronchitis or pneumonia are not represented by these extremes is sufficiently probable. The rapidity of progress observed in one instance, and its protracted duration in another, must be looked upon as exceptions to a general rule. The average duration of this primary stage will, I think, be found in a period about intermediate between the extremes above mentioned. Although speaking doubtfully on this point, I am at least certain that the rapidity of progress within a given period increases in a direct ratio with the duration of the disease. Thus, for instance, if we compare two patients, one of whom has been suffering five weeks, the other eight, and whose symptoms at the time of our comparison are as nearly alike as possible, we shall find that after a given time, say a week or fortnight, a much greater progress has been made in the latter than the former. It is thus only we can explain a circum-

stance constantly noticed by such pa-
tients, that their symptoms were at
the commencement comparatively sta-
tionary, or at most made but slight
progress; that subsequently they be-
came more and more rapid in their
course, and latterly each day has suf-
ficed to induce a well-marked increase
in every symptom. We deduce from
this fact an important practical pre-
cept—to lose no time in putting the
patient under the specific influence of
mercury, and this more especially when
the case has been at all protracted.
The delay of a few days early in its
course may be without ill effects, and
will probably, in many instances, be
advantageous, by giving time for the
employment of important preparatory
or auxiliary means: but where such
symptoms have persisted for a much
longer period, any considerable delay is
likely to be followed by serious conse-
quences ; for the disease may thus ad-
vance to such a degree as to place it
out of reach of medical assistance.

Admitting the injurious influence of
mercury upon the general constitution,
yet having determined upon its em-
ployment for the removal of local dis-
ease, an object of no slight importance
is to administer the medicine in such a
manner as to obtain to the utmost the
beneficial effects it is capable of pro-
ducing upon the lung, whilst we avoid,
as far as possible, the damage it may
do to the constitution. The more im-
mediate of the injurious consequences of
mercury are fever, great nervous irrita-
bility or disorder of the alimentary
canal, whilst the more remote, though
not less important, morbid states are,
in great measure, dependent upon, and
originate in, one or other of the three
conditions just enumerated.   To ob-
viate, then, or diminish these, as far as
practicable, is our only chance for good.
Much may be done, in the way of pre-
vention, by the employment of prepara-
tory treatment — a point too much
neglected in the present day, but to
which the attention of the profession
has recently been directed in a forcible
manner by Dr. Colles. Fever, in the
proper sense of the word, is a rare
result of mercury in the scrofulous
diathesis. It does, however, sometimes
occur, and chiefly in those individuals
who present more or fewer of the indi-
cations of plethora—who have a firm
unyielding pulse, and other indications

of the phlogistic habit.   These, it must
be confessed, are rare concomitants of
the scrofulous diathesis : they frequently
occur, however, in the form of pyrexia,
as symptomatic of local inflammatory
action ; but whether primary or secon-
dary their existence predisposes strongly
to the occurrence of mercurial fever.
In a primary or idiopathic state we
rely chiefly on aperient medicines,
saline diaphoretics, quiet, and low diet.
These means pursued for a few days
are usually sufficient to reduce all in-
flammatory disposition, and to pave the
way for the mercurial course.   But
when originating in local inflammation,
other measures, as blood-letting, either
local or general, may be required in
addition.   This feverish condition,
despite all preparation, will commonly
occur in a greater or less degree imme-
diately preceding the establishment of
mercurial action on the gums.   It is
evidenced by the usual phenomena of
pyrexia, and by an aggravation of the
local symptoms, for the cure of which
mercury has been employed.   The
application of a small number of
leeches, and the administration of saline
diaphoretics, will suffice to control
these symptoms, which, however, either
spontaneously diminish or subside on
the establishment of ptyalism.   As the
more frequent consequence of mercury
we notice nervous irritability, which,
in the scrofulous habit, it is next to
impossible wholly to avoid.   A clear
state of the intestinal canal, and a
healthy aspect of the evacuations, are
the conditions best calculated to ward
off such a state.   If not already existing,
they should, therefore, be obtained by
medicine ere the use of mercury is
commenced.   Notwithstanding this
preparatory treatment it will usually
be advisable to combine either sedatives
or narcotics with the mercurial.   A
light bitter infusion may, in some
cases, be advantageously substituted
for or combined with the sedative.
This practice is called for more parti-
cularly where, in addition to great
debility, there is a clean moist tongue,
healthy condition of the excreta, and
copious perspirations.   Sarsaparilla
often acts kindly as a soother of the
irritable state of the nervous system,
producing greater tranquillity during
the day, and more comfortable nights
than will any selection or combination
of narcotics.   To this end the infusion

of Dr. O'Beirne, prepared with lime-water, seems peculiarly adapted. Disordered condition of the alimentary canal is a frequent accompaniment and cause of the nervous irritation above mentioned. It may, however, occur *per se*, but whether alone or in combination its removal is a point of the first importance in our treatment. Where there is reason to apprehend the supervention of this condition, the exhibition of mercury should be preceded by a mild yet efficient laxative. Rhubarb, with soda and a few drops of tincture of hyoscyamus in an aromatic water, will here be found highly beneficial. Any irritation or uneasiness remaining after the free evacuation of the bowels will commonly subside in a short time under the use of alkalies with hyoscyamus and mucilage. Mercury, in its mildest form, should then be entered on, and its action may be guarded by combination with an alkali, as chalk, or with this and Dover's powder.

During the mercurial course attention to diet and regimen must be rigidly enforced. The patient should be placed on the farinacea, or milk ; animal food, fruits, vegetables, fermented, vinous, and spirituous liquors, being altogether proscribed. He should inhabit a large, airy, well-ventilated apartment, constantly maintained at one temperature, and, in addition, should wear next the skin a fine flannel garment, enveloping the whole body from neck to foot. With the preparatory and concomitant measures now recommended mercury will generally be well borne, and its use, when once commenced, must be regularly continued until the gums become affected. From an irregular and indecisive administration of this medicine ill effects will almost invariably result. Should it, therefore, manifestly disagree, its exhibition must be immediately and finally desisted from. In other instances, where but slight phenomena of disorder occur, it becomes a question, to be decided only by the circumstances of the individual case, whether, despite of these, to continue its employment, or withdraw the medicine and attempt to remove the cause upon which its injurious effects appear to have depended. In the latter instance we may, perhaps, be justified in once more resorting to its use ; but if it again disagrees, the medicine must be at once withdrawn, never more to be employed.

I have usually combined in one formula, with the mercurial, ipecacuanha and a sedative: the frequent irritative and distressing cough commonly attending this disease proving, as it does, a constant source of disquietude through the day, and of restless nights, with the results of broken rest, are indications sufficiently clear (independent of those derived from the general habit) for the administration of sedatives. Hyoscyamus or conium are those which I principally employ ; but where these fail of producing the desired effect, recourse may be had to hydrocyanic acid, belladonna, the salts of morphia, &c. Ipecacuanha acts beneficially in freeing the expectoration, and, I am inclined to think, determines the action of mercury more particularly to the bronchial mucous membrane.

However beneficially these measures may operate, it must not be forgotten that the employment of mercury is but preparatory to other and more strictly curative treatment. After the removal or suspension of local disease by mercury, an equally or even more difficult task remains of correcting the cachectic condition upon which has mainly depended the local lesion. The patient, no less than the practitioner, should remember that from extreme and immediate danger he has only been snatched by severe and almost equally dangerous means ; that the same liability to local disease exists as before, ready again to start into existence upon the application of the slightest exciting cause. One great object in administering mercury is to gain time for the employment of measures to restore the general health, by removing a local action which, allowed to continue, would give rise to such disorganization as quickly to place the patient out of the pale of cure, and long ere means calculated to work a salutary influence on the constitution could take effect. Unless this truth be fully admitted, and the practice to which it leads rigidly enforced, mercury should upon no account be administered. It does not fall within the purport of this paper to discuss the treatment best adapted to the cure of scrofulous cachexia. This has, indeed, been so fully done by Sir James Clark, in his thirteenth chapter, as to leave nothing to be desired [*].

* Pitcarne, as quoted by Allen, Synop. Univ. Med. ed. v. p. 159, Lond. pursued a practice not

With these prefatory remarks I proceed to detail the nine cases which I have subjected to the mercurial mode of treatment. Five of them have recovered; one was temporarily relieved, but died subsequently of phthisis; three experienced little or no benefit from the treatment adopted. These, with the cases of the Dublin physicians, are twenty-one in number, of which eleven were cured, three considerably benefited, six experienced no relief, and in one, the medicine disagreeing, could not obtain a fair trial.

[To be continued]

ON PERICARDITIS.

By James Douglas, A.M.

Lecturer on Anatomy, &c. &c.

[*For the London Medical Gazette.*]

(Concluded from page 112.)

When the existence of pericarditis has been determined, our difficulties are to a great extent over; not, indeed, that our treatment will always be successful, but the plan of treatment is clear. It is quite similar to that of other membranous inflammations; bleeding, general and local, mercurials, and counter-irritation, are the means to be employed. A bleeding to the extent of twelve or fourteen ounces on each of two successive days, followed by leeching, and accompanied by the administration of calomel and opium, three grains of the former and half a grain of the latter every third hour till the mouth be affected or the symptoms decline, will generally arrest the progress of its malady. When it has begun to decline, a blister over the region of the heart will accelerate the cure. After the inflammation has been completely subdued, much attention will require to be paid to the health for a considerable time, to obviate, if possible, the supervention of hypertrophy.

I will now proceed to illustrate the preceding statements by a few cases.

Case I.—James Murray, æt. 44, collier; admitted into the Glasgow Royal Infirmary, Nov. 30, 1833. For three years has been subject to violent action of heart, much increased upon exertion. Action of heart is regular, but impulse is violent, and sounds are widely heard even over both sides of back. There is a sort of creaking sound accompanying both systole and diastole. There are frequent paroxysms of pain, like the stroke of a knife, at left mamma, shooting to left arm. Pain is increased by pressing over region of heart, and has been distressing for the last ten days; for four months previous to which he had been pretty well. Pulse 120, hard, firm, and bounding. Both sound and impulse of the larger arteries, particularly subclavians, very great. That of subclavian seems to equal the impulse of an ordinary heart. Jugulars do not pulsate. He has no cough nor dyspnœa, but frequently awakens with frightful dreams. Other functions natural.

On Dec. 1st he was bled to sixteen ounces, and I wrote down the diagnosis, great hypertrophy of left ventricle, with dilatation of right.

Dec. 2d.—Blood cupped and buffy; creaking has now more of the bellows-sound, still heard in same situation. It was observed this day by Dr. Campbell, now assistant-surgeon to the First Guards, Dr. Gabriel Stokes, and Dr. Walter Dick. I added to the diagnosis, pericarditis.

He was cupped to eight ounces over the region of the heart, and had a powder containing three grains of calomel, half a grain of digitalis, and half a grain of opium, every third hour.

After using these powders for two days and a half, till his mouth became sore, they were given up, on account of their griping and purging. On Dec. 6th it is noted that pain was still excited by pressure: the frottement became less audible towards left and lower parts of precordial region. A blister was applied.

8th.—He complained of distressing palpitation, and was ordered tincture of digitalis. After this, pain abated, though still excited by pressure; and the friction-sound had nearly disappeared. On the 14th he took a longing to go home, so that we lost sight of his further progress.

Here, then, we have an example of

unlike that herein recommended: "Quamdiu tabes est in primo gradu et probabile est sanguinem non esse extravasatum ulcusve nondum factum debet ante usam decoct: ex lignis et dum purgantibus utimur adhiberi mercurius dulcis non quidem cum purgantibus simul eodem die sed sine purgantibus post aliquot dies."

pericarditis taking place without any obvious cause, cured by ordinary antiphlogistic treatment.

CASE II.—Charles Leech, æt. 19, tinsmith ; April 25th, 1834, Glasgow Royal Infirmary. Five days ago was attacked with acute rheumatism, after exposure to cold. Joints are red and swollen ; pulse full and bounding ; skin hot ; tongue furred ; thirst. Since yesterday has complained of pain in precordial region, increased on pressure. Breathlessness and cough, without any expectoration ; friction-sound heard over heart.

> V.S. ad ℥xx. statim. At bedtime an anodyne diaphoretic draught, and in the morning salts and tartar emetic.

April 27th. — Was yesterday bled again to fourteen ounces, and had calomel and opium in the evening, by which he was severely purged.

> To use a mixture, with tincture of digitalis, antimonial wine, and solution of carbonate of ammonia.

On examination to-day a friction-sound is heard all over precordial region, smaller than I have heard it in pleuritis, resembling the trituration of ointment in a mortar, very close to the ear. The two surfaces are heard to rub together both with the systolic and diastolic action. A friction-sound was heard also to the right of sternum, at its lower part, as if that angle of the cavity of the pleura, where the pleura is reflected from off the pericardium, were affected. No bellows-sound heard ; pulse 100, regular.

28th.—Sounds much the same ; feels easier.

> To begin calomel and opium again.

30th.—Was cupped yesterday over heart ; friction still audible at lower part of heart, but not much above level of nipple, indicating adhesion above that ; mouth becomes affected.

May 1st.—Complained this morning of acute pain in right side of chest, shooting through to back ; pulse irritated ; friction-sound heard with respiration in right lung, between middle of scapula and spine ; that over heart much the same ; mouth gets sore.

> V.S. ad ℥xvj. Continue calomel.

3d.—Now no frottement over heart, but slight soufflet with first sound ; complete adhesion has therefore taken place ; pulse 100, quite soft ; friction-

sound also gone from right pleura ; no pain on respiration.

> Omit the calomel.

A few days after this was dismissed cured.

In this case we have an example of extension of the disease from the synovial membrane to the pericardium, and from that to the serous investment of the lungs ; and we see all these inflammations yielding to vigorous and continued antiphlogistic treatment.

It was remarked above, that pericarditis might follow inflammation of a joint after injury. I have no notes of the following case, which illustrates this.

CASE III.—A man was admitted into the Royal Infirmary in 1835, on account of a fall on his hip. No fracture was detected ; he was leeched, and had other antiphlogistic treatment. In a fortnight he died without any obvious cause. On examining the hip, the thigh-bone was found fractured through the trochanters ; but from the form of the fracture the upper fragment was firmly wedged into the lower. No crepitus could therefore be produced ; and had the man lived, bony union must have taken place without any treatment. But a sharp edge of the bone had perforated the synovial membrane, and excited inflammation. The joint was full of reddish purulent matter, and, on opening the chest, about two ounces of matter, exactly similar, were found in the pericardium.

I will now quote from Bouillaud's work on the Heart, a case illustrating what has been called metastasis ; the disappearance of the rheumatism from the joints, and its subsequent appearance in the pleuræ and pericardium*.

CASE IV.† A young man, aged 18, of a delicate temperament, admitted into La Charité, June 27th, 1833. He had been sleeping in a damp place, and all his large joints were affected with acute rheumatism. He was repeatedly bled, and had Dover's powder.

On July 2d the pains suddenly disappeared from the joints, and in the same moment he was seized with dyspnœa, sharp darting pain in both sides of chest, with dry and frequent cough.

---

* In the cases quoted from other persons, I shall confine myself to the points illustrative of the particular part of my subject.
† Bouillaud, Maladies du Cœur, tome i. p. 495.

The existence of a double pleuro-pneumonia was ascertained by the stethoscope. Bleeding again, general and local.

4th.—Dulness of both sides below scapulæ was observed, with œgophony. By another bleeding, and the use of blisters and purgatives, the pleurisy was subdued.

About the 17th pericarditis came on. From the account it appears to have been overlooked for two or three days, for there is no notice taken of the friction-sound. After attention was drawn to it, a bellows-murmur was heard; then this disappeared, while dulness on percussion succeeded, with a gradual swelling or arching of the chest from the second to the fifth rib, with protrusion of the intercostal spaces. The sounds of the heart were heard dull, as if at a distance. Antiphlogistic treatment was persevered in, but it was three weeks before he could be dismissed.

The only remark that I would make on this case is, that it seems strange to us, on this side the channel, that, in a case of such extensive membranous inflammation, not a word is said of the use of calomel or mercury in any form.

CASE V. exhibits the supervention of pericarditis on the suppression of a cutaneous eruption. It is related by Dr. Stokes*.

Laurence Toole, æt. 5, admitted into the Meath Hospital on the 5th April, 1833. A fortnight previous to admission he had been affected with some cutaneous eruption, the nature of which could not be ascertained. This had been rapidly removed by the use of some ointment, and in a few days after its suppression he became heavy and drowsy. Respiration is laborious and hurried, 32 in the minute; countenance depressed; lips livid: pulse 130, small and jerking, but regular; heart's action extremely violent, communicating a distinct *fremissement* to the hand, as if two rough surfaces were rubbing violently upon another. Friction-sound heard both with systole and diastole.

On his death, three days after, both surfaces of the pericardium were found covered with a reticulated layer of lymph, of a reddish colour. There was no adhesion, nor no fluid.

CASE VI. is an example of pericarditis following another skin disease, scarlatina*. Mary Winters, æt. 12, a delicate-looking girl, admitted into the Hardwicke Hospital, Dublin, October 1834, for scarlatina. She became convalescent in a few days. On Nov. 10th she was suddenly attacked with great dyspnœa and sense of suffocation. Countenance anxious; sits in bed leaning forward; cannot lie down; points to epigastrium as the seat of her distress. Short, teazing, dry cough; makes no complaint of pain about heart, but when questioned says she has palpitations; has great tenderness to pressure in epigastrium, and on ribs over heart. Sounds of heart unaccompanied with friction-sound.

It would seem that here the disease was caught in the first stage, before there was any effusion of lymph. Bleeding was had recourse to, and calomel and opium. On the third day friction-sound was heard all over heart. On the sixth day it disappeared, action of heart became regular, and in two days more she was discharged.

CASE VII., from Dr. Hope's work†, is not properly an example of pericarditis, but is introduced to exemplify the diagnosis of effusion of fluid, where there were no previous signs of inflammation.

J. S., a little thin sallow man, with circumscribed patches of red on his cheeks, was received into St. George's Hospital with orthopnœa, cough, watery expectoration, ascites; face puffed and leucophlegmatic: great œdema of legs; urine scanty; pulse 110, weak; an undulating or rolling motion perceptible in precordial region.

Auscultation.—Resonance dull over an unusual extent of precordial region. Impulse of left ventricle slightly increased, but undulating, and not synchronous with the ventricular contraction, as indicated by the first sound. Sounds short, flat, and audible over the whole anterior surface of chest: neither coincides with the pulse, and they are so much alike as to be with difficulty discriminated. Left side of chest dull on percussion. Diagnosis: dilatation of left ventricle, hydropericardium, and hydrothorax.

He was treated with elaterium, calomel, and diuretics, and the hydroperi-

cardium seemed to decrease, the heart striking the ribs more distinctly. In a month he died.

Inspection.—Upwards of two pounds of serum in cavity of left pleura ; three or four ounces of bloody fluid in pericardium ; left ventricle dilated.

Dr. Hope remarks that the hydropericardium was indicated by the undulatory nature of the impulse; by its want of coincidence with the sound of the ventricular contraction ; by the sensation communicated through the stethoscope that the heart did not strike the ribs immediately, and by the extensive dulness of the precordial region on percussion.

We have seen, in several of the cases related, that when recovery took place the friction-sound disappeared ; and I have yet to shew, by a case of pericarditis dissected soon after the cure, that adhesion is the necessary termination.

CASE VIII.—As this case, that of Amelia Harris, was taken from the MEDICAL GAZETTE*, I shall only advert to its leading features. The girl, after acute rheumatism, suffered from inordinate action of the heart. The general signs were as usual, and distinct friction-sound was heard accompanying both motions of the heart. An attack of erysipelas came on and carried her off, after the friction-sound had quite disappeared, so that the normal sounds of heart only were heard. Having died exhausted by the erysipelas, the cavity of pericardium was found entirely obliterated, the opposed surfaces being glued together by recent lymph in considerable quantity; slight vegetations on aortic valves, indicating inflammation of the endocardium also. As related by the original reporter, this case exhibits very well the circumstances under which metastasis of inflammation takes place from the joints to the pericardium. The original disease had been subdued by the copious abstraction of blood, but the system was thereby rendered weak and irritable, so that the pericardium was more easily affected.

The last case (Case IX.) which I am going to relate is one shewing the co-existence of two friction sounds—one in the pericardium, the other in the pleura.

Frances Kelly,* ætat. 24, attacked, March 25, 1833, with severe arthritis. Besides the ordinary symptoms, a slight friction-sound was heard near the apex of the heart. Free bleedings were ordered, both general and local, and tartar emetic.

On the seventh day after admission she was in a state of high fever, although there was no corresponding increase of the inflammation of the joints. Dr. Stokes carefully examined the chest. The left side had become dull in its lateral and inferior portions, and the respiratory murmur had become feeble. In addition, there was a decided pleuritic friction-sound in the antero-inferior portion. That it proceeded from pleuritis was obvious from this, that it was synchronous with respiration, and ceased whenever the patient held her breath.

In using the term chronic pericarditis, I would be understood to mean, not long-protracted pericarditis, for no such thing has ever come under my observation, nor do I believe it can occur, but rather, speaking more strictly, the consequences of pericarditis — the changes which take place in the pericardium in consequence of its inflammation, when that inflammation has not proved immediately fatal.

After inflammation of the pericardium, when an increased nutrition has continued in it, we occasionally find it much thickened, becoming as it were hypertrophied. This thickening does not take place in the serous layer, but in the subserous cellular tissue; and sometimes it occurs in the fibrous layer of the bag of the pericardium. In making inspections we often find small milky opaque spots on the surface of the heart, where no complaint had been made of inflammation so far as we know. Nevertheless, there can be no doubt that these spots were originally circumscribed effusions of coagulable lymph, which have now become organized, and reduced in thickness. By laying hold of them carefully with the forceps, they can always be peeled off from the pericardium.

Sometimes we find the pericardium lined with much rough false membrane, stained of a red colour by bloody transudations, and we find a little of

this bloody fluid in the remaining cavity. It is said that even pus has been found in the pericardium, but this, as stated near the beginning, I am disposed to doubt. Accompanying these different states, we most commonly find some traces of inflammation about the lining membrane and valves, but of that it is not in my province at present to speak.

Adhesion of the free surfaces is, however, the most common consequence of pericarditis. After a cure has taken place, the false membrane gradually becomes absorbed, and what is left becomes changed into a thin layer of cellular tissue. In consequence of this adhesion the action of the heart becomes embarrassed, greater force becomes necessary to perform its functions, and hypertrophy is the result. Bouillaud speaks of atrophy of the heart from this cause, but of this I know nothing.

There is a drawing in Dr. Hope's work on Pathology, exhibiting a case of old pericarditis. The whole interior of the sac and surface of the heart are lined with a thick stratum of shaggy, highly vascular, reddish lymph, which contained nearly a pint of serum deeply tinged with blood. The left ventricle was greatly hypertrophied, and there was dilatation of both cavities. The patient was aged 52, and died of a third attack of apoplexy, a disease which very often depends upon hypertrophy.

There is also a very beautiful plate in the work of Cruveilhier, evidently of the same nature. The fluid in the sac was bloody. The surface of the heart is seen covered with lymph drawn out into points, not unlike the outside of a pine-apple. He supposes these points to have been adhesions ruptured by the effusion of blood, but I should think that doubtful.

The only physical signs of adherent pericardium which have any supporters in systematic works at the present day, are these three — increased impulse at the base of the heart, epigastric pulsation, and, depending on the same cause as this last, retraction of the intercostal spaces. The first two do not appear of much value. Mr. Aspland, in the MEDICAL GAZETTE, June 1839, notices an additional diagnostic deduced from the lessening of the mobility of the heart's apex. In a healthy individual, sitting erect, the apex of the heart

strikes at two inches below the left nipple, and one inch nearer the sternum, If lying on the left side, it strikes in a line vertical with the nipple; if lying on the right, it strikes in a line with the edge of the sternum. In adherent pericardium, this mobility, he says, is lost. [I am happy to be able to confirm the value of his diagnostic by the observation of a case, since this essay was read, where there had been pericarditis some months before. The apex of the heart did not change its place of beating by any change of the patient's position.]

Mr. Aspland supposes that a friction-sound may be present in cases of *adherent* pericardium, and gives a case of a girl who had pericarditis ending in adhesion two years before the illness which caused her death. On the second attack there were murmurs, occasioned by deposits, chiefly recent, on the valves, and there was a *frottement*, which Mr. Aspland attributes to the pericardium, although the adhesions there were *old* and *cellular*. But, in addition, there were *recent soft* adhesions of the lungs to the pleura. The frottement then existed, not *inside* the pericardium, but *outside*, between the pleura covering it and the pulmonary pleura; the pleura covering *the outside* of the pericardium moving *with the heart*, in consequence of the adhesive *inside*.

In another case, related by the same gentleman, the same complication is illustrated. A man had pericarditis, marked by the usual frottement, which disappeared as union of the inflamed surfaces took place. By and by, the epigastrium and intercostal spaces were drawn in by the contraction of the ventricles. Some days after, a marked frottement, ascending and descending, engaged the whole of the left pleural cavity, synchronous with inspiration and expiration, and depending on the motion between the lung and the inside of the chest which takes place in breathing. But there was a peculiarity, depending on the adhesion of the pericardium, that, close to the heart, the rubbing was synchronous, not with respiration, but with the action of the heart.

This friction in the pleura, caused by the action of the heart, I have myself observed in several instances, but have no notes of them.

I am not aware that it is generally

known that *old long* adhesions of the lungs may produce frottement. This fact was discovered by my friend, Dr. Walter Dick, who was a clerk in the hospital at the same time with myself, and was a most patient and diligent observer, and whose early death has no doubt robbed us of many fruits of his industry which a little longer time would have brought to maturity. He had a case in which the ascending and descending friction-sound was most distinct in a man's left side, over about the space of a half-crown, without any signs of inflammation at all. The man died of disease unconnected with his chest, and on looking at his left lung it was found attached to the costal pleura by adhesions about an inch long, for the extent indicated. An *experimentum crucis* was then resorted to: one of us moved the adherent lung, while the other listened with the stethoscope over the spot, and the circumscribed rubbing was distinctly heard.

The new cellular membrane forming the adhesions between the free surfaces of the pericardium may become the seat of tuberculous deposits. Dr. Hope relates a case of this kind. I have never seen it myself, but have no doubt of it, because I have seen a case where tubercles were found in the adhesions after pleuritis, of which I shew you. both the preparation and a drawing.

Whenever we have bone accidentally deposited, it appears to be in the cellular tissue, and generally, but not necessarily, in or adjacent to fibrous tissue. Thus, we find patches of bone in the dura mater, and occasionally in tendons and ligaments; and I have specimens of it in the subserous cellular tissue of the pleura. In the same way we find it in the pericardium; in some cases in the subserous cellular tissue; and in other cases in the adventitious cellular layer connecting the serous surfaces together, in cases of long-adherent pericardium.

Mr. Aspland, whom I have quoted before, relates a case in the 24th vol. of the MEDICAL GAZETTE, to which I shall briefly allude. A young sailor had the signs of adherent pericardium, as given a few pages back, and on inspection there were found in the adhesions several patches of bone, the largest the size of a penny piece. The mitral valve was found thickened, its tendons

partly ossified, and four of them ruptured, the torn ends being covered with coagulable lymph. The reporter attributes the sudden death to this lesion. I do not think that this could be the case, as I have the preparation of a heart here in which the condition of the mitral valve is precisely similar to that described, and where the patency of the auriculo-ventricular orifice was ascertained by me with the stethoscope a considerable time before the patient died.

Bouillaud gives a case where on the inside of the pericardium was found a patch of cartilaginous texture, containing bony granules, exactly like that which I now place before you, taken from the upper surface of the diaphragm. In another of his cases there were ossifications both between the serous membrane and the fibrous layer of the pericardium, and between the serous membrane and the muscular substance of the heart. One of these latter, placed near the apex of the heart, had, by its friction, literally worn a hole in the bag of the pericardium, and caused an abscess on the surface of the diaphragm. I shew you, dried and in turpentine, a specimen with two patches of bone between the muscular substance of the serous covering, the largest about the size of a sixpence. I am indebted to Dr. R. Paterson, in Anderston, for a preparation exhibiting the most extensive ossification of the pericardium which I have ever seen. The band of bone, about an inch and a half in breadth, almost completely surrounds the heart. When recent, I examined it, and found it placed between the muscular substance and its serous investment. The patient had suffered from pericarditis about nine years before his death, and the surfaces were universally adherent.

Bouillaud gives a case of a cancerous tumor of the mediastinum encroaching upon and becoming incorporated with the pericardium; but of such I have no personal knowledge.

CO-EXISTENCE OF
OVARIAN DROPSY & PREGNANCY.

To the Editor of the Medical Gazette.

SIR,

IF the following case be worthy a corner of your valuable journal, by its inser-

tion you will much oblige, your obedient servant,

J. FOSSE HARDING,
M.R.C.S.

13, Spencer Street,
Northampton Square.
Oct. 9, 1840.

In February, 1839, Mrs. K., æt. 27, consulted me, as she had been labouring under ovarian dropsy for several months, commencing shortly after her second confinement. She had been under the care of Dr. Maybank, of Guilford, who finding the disease not to give way from the measures he had considered advisable, had requested her to get the fluid drawn off, for which purpose she came to town, and called on me as her general medical attendant. I wished her still to try the effects of medicine, which she did, with some relief for a short period only; and in three months from the time of seeing me, I had recourse to the last resource of an operation, drawing off two gallons of a coffee-coloured fluid. In the course of a week the patient sufficiently recovered to go into the country. I prescribed for her what I considered advisable— a mercurial course, with iodine,— without any benefit, and in six months from the last operation I drew off two gallons and a half of fluid, of the same character as the last. On bandaging the abdomen I felt, as I then supposed, the enlarged ovarium. She again filled very rapidly, and I was under the necessity of affording her relief by an operation in the end of February last; but I experienced the greatest difficulty in drawing off the fluid, amounting to 14 quarts, of a chocolate colour, being more than two hours under the operation. I then examined the abdomen, and, to my surprise, found so great an enlargement, as I was led to suppose, of the ovarium; yet still, from other symptoms which afterwards more plainly showed themselves, I was very suspicious of her being pregnant; but neither the stethoscope nor manual examination satisfied me: I therefore advised her friends to get a second opinion, which they did, of a very eminent obstetric physician, whose decision was, that he did not consider that pregnancy existed, and wished for an operation as early as possible. The patient now was suffering the greatest inconvenience from the great distension of the abdomen; so much so, that she begged me again to relieve

her by an operation; but my suspicions still existing, I declined doing so—at least for the present.

I was summoned a few days since by a hurrying message that my patient was dying. On my arrival I found she had been delivered of a full-grown healthy female infant, and is now doing exceedingly well, and suckling the infant; but in the course of a few weeks she will require the evacuation of the fluid, which is rapidly accumulating. I have given you the particulars of the case, as a rare instance of pregnancy and ovarian dropsy existing at the same time, and showing how guarded we ought to be, when any doubt arises, ere we proceed to an operation.

MEDICAL GAZETTE.

Friday, October 23, 1840.

PHYSICIANS IN FOREIGN COUNTRIES—DR. MARC.

ADAM SMITH observes, that after all that has been said of the fickleness of human nature, man is the most difficult of all commodities to transport. He means that although many or most persons show an inclination to change their position, yet, when it comes to the push—when the proposal is made to quit their country, perhaps for ever, the majority shrink from the offer.

Nescio quâ natale solum dulcedine cunctos
Ducit, et immemores non sinit esse sui!

This is perfectly true; and there is another reason for the unwillingness. Many kinds of merit bear a local stamp, and resemble certain wines, which, though delicious when drunk on the spot, cannot stand a distant carriage. It might appear at first sight that medical talent would be eminently transplantable; and that he who possessed the art of curing disease might practise it in any region sufficiently opulent to reward his skill. The facts,

however, are far otherwise. Indeed, it is precisely in countries whose advance in wealth and civilization has engendered the greatest attachment to their own usages, that such a translation of talent is the most difficult. In England, France, Germany, and Italy, it is natural for the natives to place the most perfect confidence in their own physicians, and to turn aside from foreigners. If physic consisted merely in the solution of medical problems, natives and foreigners would meet on a more equal footing ; but the successful practitioner must cure not only *tutò et celeriter*, but *jucundè ;* he must have the most perfect knowledge of the social laws which he is to obey ; while, with a foreigner, half a life-time often passes away, and leaves him still in the elements of this necessary art. But if the country is decidedly outrun in the European race for civilization, these reasons no longer hold good. There is no cause why the Italian should prefer a French to a Tuscan physician, and many why he should not ; but it is obvious that, for some time to come, the higher classes of St. Petersburgh will continue to employ English or German physicians instead of their own. While England for so many centuries was behind the continent, the same preference naturally obtained ; and we find it recorded that John a Gaddesden, the court physician in the reign of Edward II., was the first Englishman who had reached that dignity. Even so late as the time of Charles I., the court physician, Sir Theodore Mayerne, was a Frenchman. The change in this point is entire, and it must be remarkable talent, indeed, which can enable a foreign physician to obtain practice among the fastidious natives of this island. The difference of language is, no doubt, a principal ingredient in the difficulty ; particularly when we recollect that ignorance of a language

implies ignorance of the usages of which it is the expression.

The difficulty is almost as great in France as in England. For although some knowledge of French forms a part of education throughout Europe, yet even the traveller, whose sole occupation in France is to amuse himself, commonly finds how slight and insufficient that knowledge is. Much more, then, will this be felt by him who endeavours to earn a subsistence there, and who no longer sees around him the smiling recipients of his cash, but rivals willing to misinterpret. The foreign physician, therefore, who succeeds in establishing himself in practice among the natives of France, gives evidence of the most consummate tact, and might, without further proof, be admitted among the chosen few whose high talents are beyond dispute. The phenomenon is, therefore, rare ; but France has lately lost a living example of the possibility of its occurrence.

Dr. Marc, who succeeded in raising himself from the plains of the profession to its social summit (having become physician to the King of the French), was born at Amsterdam in 1771, of a German father and Dutch mother. He studied medicine in Germany, and took his degree at Erlangen in 1792. He then devoted himself to deep clinical study at Vienna, and afterwards proceeded to Bamberg, where his uncle, Dr. Marcus, a name favourably known in science, was his guide in practice. In 1797 he went to France for the first time, and contributed, with Corvisart, Alibert, Bichat, &c., to found the *Société médicale d'émulation.* After being necessarily absent, on account of the death of his father, in 1798, he finally settled in France. " C'est dans cette heureuse terre, *magna parens virûm,* qu'il voulut se marier, vivre, travailler, et mourir*."

---

* Gazette Médicale, July 18, 1840.

This determination shewed great vigour of mind. He was not acquainted with France, which had been recently shaken to its foundations by war and political troubles. Marc was twenty-nine years old, continues his biographer; and although extremely well-informed, his name was still obscure, and his University distinctions totally unknown. He was not familiar with the French language; and a crowd of difficulties, embarrassments, and prejudices, flocked to meet him on every side. If we add to all this, that his family had experienced great reverses of fortune, and that his own property was almost gone, we must acknowledge that he had " a sea of troubles " to contend against, and must allow the greater credit to him who could, " by opposing, end them." To know the precise intensity of the difficulties which a foreign physician must encounter in France, it is necessary to have tried the experiment oneself; we may understand the genus of his perplexities, but scarcely the species. In truth, the exact position of the *médecin* in France is not easy to make out at a distance; he neither corresponds to our physician, nor to our general practitioner, but is something between the two. In remote country districts he is allowed to sell physic; but this permission depends, we believe, on the distance of the nearest druggist; so that the approach of another *pharmacien* would deprive the D.M.P. of this branch of his practice.

In Paris, however, as far as can be seen through the misrepresentations of a satire *, the physician's hopes of getting on might be attributed to many a London doctor. His wish to be physician to a public institution, and to be noticed in the journals, are based on human nature, and are not limited to

any single city; but when the French satirist talks of the doctor's violent attempts to become known by planting tulips, or collecting bad pictures, the sketch seems to partake largely of that species of caricature, which cannot be called an exaggeration, simply because it resembles nothing at all. There, as here, a carriage is supposed to be necessary. " Faire son chemin à pied quand on a la renommée pour but, c'est vouloir arriver tard, ou plutôt n'arriver jamais; on prend donc une voiture."

Such, however, were not the arts of Dr. Marc; he belonged to a higher sphere, and did not aim at a tricky success. Truth, skill, and earnestness, were his merits; and to these he added the confidence which springs from the consciousness of desert, and which has a tendency to produce the success by which, in turn, it is infallibly increased. Yet, strange to say, he retired for some time from the profession. Two things disgusted him with it; one being the responsibility which hangs over the head of the French practitioner; the other, the custom of the physician sending in his bill.

He then became a manufacturer of chemical substances; but in this pursuit he failed altogether, and was ruined, or nearly so; for though his talents were great, he had not the peculiar tact necessary for business.

This was a critical period of his life, and an ordinary looker-on might have thought that Marc was unadapted for any common occupation; that his apprehension was too fine for the business of real life, and that it was his destiny, in Goldsmith's phrase, to " eat mutton cold, and cut blocks with a razor." It was not so, however; he returned to his profession, and his struggles were ultimately rewarded by the most signal success. Though he worked day and night for his family, he refused gain at

* Les Français : Mœurs Contemporaines. Le Médecin. Par M. L. Roux.

the price of meanness. When he had ascertained that sulphate of iron was a good substitute for bark (a most valuable discovery in 1810) he rejected with disdain the proposal which was made him to keep the remedy secret; for he felt that the duty of a physician to science and humanity was to be set before fortune.

Some of his best writings were the essay entitled, *La vaccine soumise aux simples lumières de la raison*, his instructions concerning the asphyxia of the drowned, and various articles on public hygiene.

The same correctness of reasoning which was exhibited in his works was shown when he spoke in the learned societies to which he belonged. Dr. Marc had the moderation which results from the habit of reflection, as well as from sobriety of opinions. His biographer says that as Marc knew that nothing is more uncommon than gaining a vote by a speech, he spoke simply and deliberately, but with great argumentative force. To this he immediately adds, that by these means, without effort, without prolixity, and without oratorical hypocrisy, he almost always succeeded in obtaining victory for his opinions. From this it would appear, that the most uncommon of occurrences was with Marc an everyday event. We suppose the truth to lie between the extremes of this paradox. On the one hand, it is probable that when a man is known to be honest, and to speak for truth rather than victory, he more often gains votes than is commonly imagined; and on the other, that when the sense of the assembly was decidedly against him, even Marc's quiet good sense would rarely have gained the day.

When controversy waxed hot, and questions became irritating, (" ce qui arrive parfois dans les assemblées de confrères,") Marc held his tongue,

feeling assured that there are circumstances, where, as a celebrated man has said, to be silent is to speak clearly.

Deep as were his studies, and great as were his sacrifices to duty, he knew how to unbend the bow, and, in the language of Horace, "to indulge his genius;" indeed, according to the *Gazette Médicale*, his gaiety was sometimes in excess. He often extolled the efficacy of Bassompierre's remedy against the plague and reserve, to wit a glass of good wine, though he never overstepped the limits of the strictest sobriety.

He died on the 12th of January, 1840, just as he had completed his work entitled "De la folie considerée dans ses rapports avec les questions médicojudiciaires." His calm and resigned death, says his biographer, was like the last reflection of the virtues which had honoured his life; it proved the strength and sincerity of his principles.

The remarkable success of this physician in a foreign land is an additional instance of the rewards which attend on well-directed talent and unceasing industry; and is thus an answer at once to the satirist and the hypochondriac.

A FEW REMARKS ON
MR. WARBURTON'S MEDICAL
PROFESSION BILL.

Castle Hedingham, Essex,
October 14, 1840.

To the Editor of the Medical Gazette.

Sir,

At length we are favoured with Mr. Warburton's Medical Profession Bill, and, after anxiously waiting nearly or quite seven years, what have we got? A bill for properly regulating the medical profession—supporting the respectability of its members, and defending them from the numerous intruders with whom they have long been, and still are, most shamefully pestered? No—far from it: instead of this we have a bill containing fifty-nine complicated clauses, not one of which, in my humble opinion, will benefit the profession one iota, but, on the contrary, shamefully debase it; and I really think we cannot do better than thank

Mr. Warburton for the pains he has taken, (for undoubtedly pains he has taken), and respectfully request him to withdraw his proposed measure.

The Bill commences with a declaration, " That it is expedient that all male persons practising medicine in the United Kingdom should be registered, &c., &c." Now I would ask Mr. Warburton, or any other person concerned, what is the intent or use of this registration? Are we not already registered? the physicians and surgeons in their respective colleges, and the apothecaries in the rolls or books of their own company. These lists are regularly printed (those of the College of Surgeons, I believe, annually), and may be easily obtained; the names and residences of the principal physicians and surgeons are inserted in the Court Kalendar, and, if it be considered necessary to publish the names and residences of every practitioner in her Majesty's dominions, it may surely be done just as easily as a list of the Army or Navy: but do the public require any further registration than what they now possess? The names of the heads of the profession are so well known throughout the kingdom, indeed throughout the world, that I have not the least doubt, were a letter written in China or Japan, and merely addressed to Sir Astley Cooper, or to Sir Benjamin Brodie — England, such letter would very readily reach its proper destination. With regard to the provincial practitioners, every individual is well known in his own neighbourhood, and very many of them far beyond, and I believe I may very safely assert that each and all of them are perfectly satisfied with the present mode in which their names are registered in the several institutions whence they have obtained their permission or license to practise. We require no further registration; but we require that each and all the several medical institutions in the United Kingdom should be legally authorized to enforce an obedience to their laws; that their members should be entitled to claim a suitable remuneration for their services, and to prevent improper or unauthorized persons from practising any branch of the medical profession.

For this said useless registration, which it seems is to be compulsory, an annual tax is to be imposed " to pay the costs of administering the Act; any deficiency to be specially supplied by Parliament." But the chief use of this tax is, not in any way to benefit the members of the medical profession—God help them, poor slaves!—but to create a fund for paying a gang of registrars and sub-registrars to be appointed throughout the United Kingdom, who, like the Assistant Poor Law Commissioners, will doubtless be paid their hundreds and thousands per annum for their worse than nonsensical services.

The duties of the sub-registrars are described in the fourth and fifth clauses, and require " the medical practitioner to supply them a schedule of name, address, branch of medicine, and nature and dates of his qualifications." " But," says the clause, (" hear it, all ye physicians, fellows and members of our Universities and Colleges—hear it all ye members of the Royal College of Surgeons—attend to it all ye members of the Worshipful Company of Apothecaries, and all ye students, physicians, and surgeons in embryo, who, at this present moment, are fagging hard at your studies, in order to gain the diploma—attend to, admire at, and weep over this clause; but, above all, ye chemists, druggists, quacks, mountebanks, and pretenders, read it and rejoice—

Throw up your caps, loud Io Pæans sing,
Till wakened echoes bid the welkin ring;

for this crowns all)—" But," says the clause, " if he do not hold a medical qualification, then, whether it is as being a chemist and druggist that he practises medicine in chief, and if under the Apothecaries' act, or a right acquired by usage before that act was passed; or whether he practises medicine in chief, without either holding a medical qualification, or being a chemist and druggist."

Here's a pretty pack—here's a rare set, to be registered and called the medical practitioners of Great Britain! But who can possibly be meant by this last class? Those who " practise medicine in chief, without either holding a medical qualification, or being a chemist and druggist." Probably any quack fellow of the Morison or St. John Long School—the physician or surgeon's footman or groom, perhaps—or the lad who sweeps the apothecary's or druggist's shop, and carries out his medicine.

As I before observed, this registration is to be compulsory, for Clause 17 declares " it shall not be lawful for any unregistered person, even although he hold a medical qualification, to act as a medical practitioner, in part of the United Kingdom; any custom, or thing contained in any statute, gift, grant, or deed, or by any by-law, regulation, or statute of any corporate body to the contrary notwithstanding." So that the highest medical degree will not entitle a man to practise without registration, yet any man may claim to be registered, and when registered may practise in any part of Her Majesty's dominions without any medical degree or qualification whatever.

I may have mistaken the meaning of the clause, but I have not misquoted the words, and to me it appears the most daring, barefaced encouragement of quackery, and the grossest insult to our Universities and Colleges I ever met with. What! shall a number of highly-educated gentlemen, who have regularly taken

their degrees in medicine, be debarred from
practice unless they are classed and registered
with a set of paltry adventurers possessing
no medical qualification whatever? Truly,
Mr. Warburton must consider us a set of sad
nincompoops. Mr. Warburton's medical
profession bill, forsooth!—call it rather Mr.
Warburton's medical extinguisher, for he
seems inclined to use it as such to all our
old institutions, which he would put out with
as much indifference as he would so many
candles.

But, good Mr. Warburton, pri'thee have a
care; these said old institutions have pro-
duced, and still continue to produce, not a
few men of rea lgentlemanly spirit, " bright,
and shining lights," which, without espe-
cial caution on your part will, most assuredly,
very severely burn your fingers.

In addition to this registration scheme,
the 19th clause proposes that " three medi-
cal councils'shall be constituted, one for Eng-
land, one for Scotland, and one for Ireland,
each to consist of 36 councillors, 12 of whom
shall be non-medical men, nominated and
appointed by the Secretary of State for the
Home Department, and of these three coun-
cils of 108 persons, 12 members are to be
annually chosen from each council to form
a United Medical Senate of 36 persons. Of
each 12, four persons are to be chosen from
the non-medical division."

Why non-medical men are to be admitted
members of a council whose office is to make
by-laws and regulate the affairs of the medical
profession, I am at a loss to conceive, and
why the Secretary of State is to interfere in
the business I am equally unable to com-
prehend; but the whole bill, from begin-
ning to end, is a trumpery, disgusting
farrago, and the most shameful insult to the
medical profession I ever perused: it is,
doubtless, intended to overthrow all the
existing medical and surgical colleges and
universities in the United Kingdom. But
this, I trust, will not be easily accomplished.
Let me beg every member of the Royal
College of Surgeons in London to bear in
mind the oath he took when he obtained his
diploma, to " support to the utmost of his
power the dignity and welfare of the Col-
lege." The heads of the profession, the
several members of the councils of the Royal
Colleges, both of Physicians and Surgeons,
throughout Her Majesty's dominions, will, I
have no doubt, view the matter in its proper
light, and pursue such course as will enable
them to crush the filthy monster ere it breathe.

Having, sir, thus done what I conceive to
be my duty, in expressing the faults of this
bill, I beg leave to conclude, by subscribing
myself

Your very obedient servant,
G. HARVEY.

EIGHTEEN-PENNY VACCINATION.

To the Editor of the Medical Gazette.

SIR,

THE Guardians of the Brentford Union
having, on the 30th ult., addressed a circular
to the resident general practitioners, in-
quiring whether they would vaccinate upon
the terms stated in page 89 of the circular
of the Poor Law Commissioners (viz. at
eighteenpence per case), a meeting of such
practitioners took place on the 9th inst.;
and, to obtain the concurrence of some who
were absent from the first meeting, a second
was held yesterday. The result is, that of
the thirty-three general practitioners residing
within the Union, twenty-seven have sub-
scribed the declaration, of which, at their
request, I forward a copy for your notice or
insertion; *one*,—though, as *a guardian*, dis-
qualified from joining in an offer to con-
tract,—is well known to be favourable to
the higher charge, and the remaining five,—
although by various causes prevented from
signing,—are virtually pledged not to accede
to the present terms of the Commissioners.

It is earnestly to be hoped that an ex-
ample of such perfect unanimity will not be
lost on the medical men of other Unions.

I am, sir,
Your very obedient servant,
FRANCIS A. B. BONNEY,
Hon. Sec. to the Meetings.
Brentford, Oct. 14th, 1840.

(COPY.)
WE, the undersigned Medical Practitioners,
residing in the Brentford Union, do hereby
declare our adhesion to the following Reso-
lution, which was unanimously adopted at a
meeting of Medical Practitioners residing in
the said Union, on Friday, the 9th day of
October, 1840, viz. :—

" Resolved that this Meeting consider
that the sum of one shilling and sixpence is
not a sufficient remuneration per case, under
the Vaccination Act, recollecting that all
classes may avail themselves of it; and that
an answer be returned to the Board of
Guardians, respectfully declining their offer,
and at the same time proposing to undertake
the duties at two shillings and sixpence per
case.

(Here follow the 27 signatures.)

NORTH OF ENGLAND MEDICAL ASSOCIATION.

AT the monthly meeting of the Council of
this Association, held on Wednesday, Oct.
14th, the following resolutions were adopted
unanimously :—

" That in the opinion of this meeting,
the Medical Profession Bill of Mr. War-

burton, M.P. is not suited to the wants of the community nor to the wishes of the members of the medical profession."

"That the Secretary be requested to communicate the foregoing resolution to the editors of the London medical journals, and to the Medical Associations of the United Kingdom."

WESTMINSTER MEDICAL SOCIETY.

This Society met for the first time this season on Saturday, the 17th, at the Exeter-Hall Rooms in the Strand. The meetings are to be continued every Saturday evening during the season, at the same place. It is not our intention to report the proceedings unless on extraordinary occasions.

TESTIMONIAL TO SIR B. BRODIE.

On Tuesday last, a meeting of the subscribers to the testimonial to Sir Benjamin Brodie took place in St. George's Hospital, Mr. Fuller in the chair. The secretary, Mr. C. Hawkins, read the report, stating that 343 subscribers had enrolled their names, and that the amount of subscriptions averaged £360. The committee recommended that the testimonial should be as lasting and public as possible, and came to the conclusion of suggesting to the meeting one which, while it marked their admiration of the talents and character of Sir B. Brodie, would also conduce to the advancement of the interests of the surgical profession; and with these objects in view they proposed for the concurrence of the meeting, that a die be made, having a profile of Sir Benjamin Brodie on one side, and an inscription on the reverse, from which a model might be taken to be annually awarded as a surgical prize, to be called "The Brodie Testimonial Prize," to be contended for by the whole profession, and that the distribution of the prize should be committed to the College of Surgeons in London, and that that body be solicited to undertake the task of awarding the prize, the amount and value of which would depend upon the amount of subscriptions.

On the motion that the report be received, it was moved, seconded, and, on a division carried, that the awarding of the prize should rest with the officers of St. George's Hospital; when a committee was appointed to carry the spirit of the report, with the amendment, into operation. The thanks of the meeting were then voted to the chairman.

FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

(From a Correspondent.)

It had long been a point in dispute whether the holders of the degrees of "Doctor in Medicine" and "Master in Surgery," were entitled to act as general practitioners within the counties of Lanark, Renfrew, Ayr, and Dumbarton, without submitting to an examination and being licensed by the Faculty of Physicians and Surgeons of Glasgow. The University of Glasgow maintained the affirmative, contending that their Degrees conferred such title to practise in any department of the healing art within these bounds as well as elsewhere; but the Faculty, whilst they admitted that holders of the Degree of Doctor in Medicine from *any* famous university conferred the right of practising as a *physician* every where, asserted that, in the terms of a Royal Charter, granted to their predecessors and confirmed by act of parliament, they were constituted a corporation, with the special charge of the districts above referred to, to take care that no unfit person should practise the healing art therein; that it was their duty to call all practitioners within these counties before them; if acting as physicians to cause them to exhibit their testimonials; and if acting as general practitioners to cause them to submit to an examination, and if found qualified, to confer their license accordingly.

After a lengthened litigation before the Supreme Court in Scotland, and latterly before the House of Peers, it was definitively settled on the 7th of August last, by the award of that right honourable House—

1. That the Faculty of Physicians and Surgeons of Glasgow are a legally constituted corporation, agreeably to their charter from the crown in 1599, duly ratified by parliament in 1672.

2. That as such the Faculty have power to debar from the practice of surgery all persons who have not submitted to examination before them, and who have not obtained their license to practise.

3. That the Degree of Doctor of Physic from a University where medicine is taught, does not enable the graduate to practise surgery within the bounds specified in the charter.

4. That in like manner a testimonial of skill in surgery, from a university where surgery is taught, or the Degree of Master in Surgery recently introduced into the University of Glasgow, does not entitle the possessor to practise surgery within these bounds.

The Lords of Sessions summed up their decision in these four very distinct propo-

sitions, and the House of Peers confirmed this decision.

The Faculty of Physicians and Surgeons of Glasgow, therefore, are now confirmed by the highest legal sanction in the empire, in their rights as a corporation, having jurisdiction over the counties of Lanark, Renfrew, Ayr, and Dumbarton, and as bearing a Commission, under royal and parliamentary authority, to debar, by fine and interdict, all persons attempting to practise medicine within these bounds without shewing proper testimonials, or to practise surgery without their examination and license ; which examination cannot be legally dispensed with or superseded on account of the persons so attempting to practise surgery being holders of one or other of the academic honours of Doctor in Medicine or Master in Surgery, or being possessed of any other diploma, certificate, or testimonial whatever.

ANNUAL EXAMINATION
OF THE
CANDIDATES FOR THE BOTANICAL
PRIZES,
GIVEN BY THE COMPANY OF APOTHECARIES.

Examination paper, October 14*th,* 1840.
Hours from 10 A.M. till 10 P.M.

1. Describe the elementary organs of plants, with their modifications.

2. State the opinions of Schleiden with respect to the chemical composition of the elementary organs, and of the subsequent deposits.

3. What are the special properties of cellular tissue ?

4. What is the structure of the bark ?

5. What are the uses of the bark ?

6. Describe the usual structure of the stem of an exogen : the structure of the stem of *Phytocrene gigantea :* of the Coniferæ : the Cycadaceæ : and of arborescent ferns.

7. How is wood formed ?

8. What are the functions of the leaves ?

9. Name any instance in which spiral vessels are supposed to perform the function of transmitting fluids.

10. Describe the *general* and *special* circulation of the sap.

11. What is the cause of the motion of the sap ?

12. What are buds ; and in what do they differ ; firstly, according to their situations ; and secondly, according to their contents.

13. Describe the organs which the buds evolve ; name each stage of metamorphosis ; and state which parts of the several organs are analogous to each other.

14. How is the ovule developed in Santalaceæ and Loranthaceæ ?

15. What is the structure of the embryo ?

16. What are the elementary substances which are met with in plants ?

17. What are the conditions necessary for the germination of a seed, and the physical and chemical changes which accompany that process ?

18. What alterations take place in the ripening of fruits ?

19. What are the names and essential characters of the classes of the vegetable kingdom, arranged according to the natural system ?

20. State the essential characters and medical properties of the following natural orders :—

1. Ranunculaceæ and its sub-orders. 2. Umbelliferæ and its sub-orders. 3. Myrtaceæ. 4. Cucurbitaceæ. 5. Passifloraceæ. 6. Guttiferæ. 7. Sapindaceæ. 8. Euphorbiaceæ. 9. Rutaceæ. 10. Melanthaceæ. 11. Amaryllidaceæ. 12. Smilaceæ. 13. Filices. 14. Fungi. 15. Algæ.

21. Give the generic characters of *Conium, Œnanthe, Æthusa, Solanum, Nicotiana, Atropa, Datura,* and *Hyoscyamus.*

22. Describe fully (in Latin) the plants numbered 1, 2, 3, 4 ; and refer them to their proper natural orders.

[The plants were—1. Lechenaultia formosa. 2. Erica taxifolia. 3. Crowea latifolia. 4. Westringia longifolia.]

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture VI.

Causes of disease: distinction between predisposing and exciting causes. Enumeration of causes, as connected with the atmosphere—food and drink—poisons—exercise—sleep—mental and moral conditions—hereditary tendencies — malformations. Temperature. Effects of heat and of cold.

The *causes of disease* are commonly arranged under three heads—as predisposing, exciting, or proximate.

Of these three, the last mentioned, or the *proximate* cause, is nothing else than the actual disease itself—the actual condition of that part, or of those parts of the body, from which the whole train of morbid phenomena essentially flows. When we know those parts, and that condition, we name the disease accordingly. When we do not, we call the complaint after the group of symptoms by which it is characterized. The term proximate cause is therefore an unnecessary term :—it is moreover, to learners, a puzzling term, and tends to give to the consideration of disease a scholastic and repulsive aspect. I wish you to get into the habit of contemplating the whole science of medicine under its simplest and plainest form. I am sure we may very well abolish the term proximate cause altogether ; and having now given an explanation of its meaning, for your guidance when you meet with it in books, I shall never employ it, in these

lectures, except perhaps in a quotation, again.

In strictness of language, one event is held to be the cause of another event which follows it, when the first being absent, the second never occurs—and the first being present, the second never fails to occur, unless some other event intervene to prevent it. But the causes of disease will not bear to be spoken of after so strict a fashion. We perceive that certain external circumstances (*quæ nos circumstant*) often precede such and such diseases ; and that the diseases seldom happen when these circumstances are not previously observable ; and we begin to regard those circumstances as exciting causes of those diseases. We find that the diseases are much more frequent among persons known to have been exposed to the agency of the presumed causes, than among persons who are not known to have been so exposed. The evidence at first is presumptive only. But the more uniform their conjunction, and the more rare their disjunction, the more confidently do we ascribe to the two consecutive events the relation of cause and effect. By this kind of observation a number of exciting causes of disease have been clearly established to be such.

But recollect, certain circumstances being present, such and such diseases do *often*, not *always*, follow. Some persons are more liable to be affected by the operation of many of these ascertained causes than others are ; and the same persons more liable to be influenced by the same cause at one time than at another. And special circumstances, existing in particular cases, will be found to account for this variable operation of known exciting causes upon the bodily health. These special circumstances may properly be called *predisposing causes.* Thus, of a score persons exposed to the same noxious influence—to the combined influence of wet and cold during a shipwreck for example—one shall have catarrh, another rheumatism,

a third pleurisy, a fourth ophthalmia, a fifth inflammation of the bowels, and fifteen shall escape without any illness at all. A man shall do that with impunity to-day, which shall put his life in jeopardy when he repeats it next week. It is not therefore the exciting cause *alone* that in all cases determines the disease. Something—nay much—or all —will frequently depend upon the *condition of the body* at the time when the exciting cause is applied :—and this condition of the body, which we call *predisposition*, will depend upon circumstances then or previously in operation—and these circumstances are, in our language, *predisposing causes.*

Do not confound, as many seem to do, the predisposition with the circumstances creating it. The predisposition is a certain state of the body—the predisposing cause is what produces that state. The *cause* of the predisposition is the *predisposing cause* of the disease. A predisposing cause may therefore be *defined* to be anything whatever which has had such a previous influence on the body as to have put it in a condition of greater susceptibility to the exciting cause of the particular disease.

It is sometimes difficult, or impossible, to say of a given cause whether it ought to be ranked among the exciting or the predisposing causes : whether it has prepared the system for being affected by some other agent, or whether it has itself produced the disease ; but for the most part the distinction is real—and sufficiently well marked—and of great importance to be attended to.

Disease may sometimes be averted, even in despite of strong and fixed predisposition to it, if we know, and can guard against the agencies by which it is capable of being excited. A man may inherit a proclivity to consumption, yet fortunately escape that fatal complaint by timely removal to a warm and equable climate, and by other suitable precautions ; that is, by avoiding whatever tends to rouse the dormant tendency into action. On the other hand, disease may often be warded off, notwithstanding the presence and application of its exciting cause, when its predisposing causes are ascertained and can be prevented. In proportion as the body is weakened or exhausted, it yields more readily to the pernicious influence of contagion, or malaria ; but by obviating all causes of debility, and fortifying the system, we walk with comparative security amid surrounding pestilence.

Diseases sometimes occur, when no exciting cause, when no cause at all, has been apparent. All that we can say of such cases (which are not, however, very frequent) is, that the causes have not hitherto been discovered.

Now the ascertained causes of disease are many and various. Whatever ministers to life, health, or enjoyment, may become the medium, under changing circumstances, of pain, disease, or death. The atmosphere, in which we are constantly immersed, is full of dangers. Both the organic and the inorganic world of matter around us abound in poisons ; they lurk in our very food, which becomes pernicious when taken in excess, or when it consists of certain substances, or certain admixtures of substances : so that there really was much truth, as well as some humour, in the startling motto to Mr. Accum's book on adulterations—" *There is death in the pot.*" Our passions and emotions also, nay even some of our better impulses, when strained or perverted, tend to our physical destruction. The seeds of our decay are within as well as around us.

Let us enumerate, however, a little more particularly, the various known sources of disease, with the view of making, afterwards, a few practical comments upon some of them.

Chemical and mechanical injuries. — I shall pass over, in this enumeration, nearly all chemical and mechanical injuries—inasmuch as these belong to surgery.

Atmospheric influences.—Under the head of atmospherical causes, we shall find that those varieties in the state of the air which proceed from mere differences of degree in its natural qualities may be productive of disease. Such are—extremes of heat and cold ; sudden variations of temperature ; excessive moisture or excessive dryness ; different electric conditions ; differences of pressure, as measured by the barometer ; a deficiency of light.

Again, the atmosphere may be a source of disease in consequence of its being loaded with impurities. Malaria—contagions of various kinds—and noxious gases in general, may be considered as so many poisons.

Nutriment.—Under the head of *nutriment* we may place the use of food of which the quality is bad and hurtful ; this cause also strictly belongs to the class of poisons :— again, an insufficient supply of healthy food : —a still more common cause is *excess* in *eating* and *intemperance* in *drinking.*

Poisons.—The numerous *poisons* which are not comprehended under either of the foregoing heads are also prolific sources of disease.

Employments —Another great class among the causes of disease might be formed by considering together the influence of various *trades and avocations* which are directly injurious to the health of those who pursue them.

Exercise.—We know, by ample experience, that a certain amount of bodily *exercise* is essential to good health. We see

the evil consequences of much overstepping that amount, in the deformities and disorders that result from too severe and continued labour. But a much more numerous train of complaints follows the opposite state—that in which, from indolence, or from necessity, but *little* exercise is used.

Sleep.— Excessive indulgence in *sleep* on the one hand, and long continued want or interruption of repose on the other, are apt to give rise to serious maladies.

Mental and moral causes.—Very many diseases have a mental origin. Excessive intellectual toil—the domination of violent passions—the frequent recurrence of strong mental emotions—vicious and exhausting indulgences,—each and all will sap the strength, and grievously impair the health of the body : and perhaps there is no cause of corporeal disease more clearly made out, or more certainly effective, than a continuance of mental anxiety and distress.

Hereditary tendencies to disease, and malformations.—When we add to this catalogue of the sources of disease all those morbid tendencies which are *hereditary*—and those which flow from original *malformation*, and are congenital—we shall have a tolerably complete list of the manifold dangers to which our mortal frames are continually liable.

There are several points of view under which the consideration of these causes of disease might be shown to be interesting. We might enquire, for example, which of them are commonly predisposing, which exciting causes ; and what are the circumstances which are found to render the same agent at one time merely a predisposing, and at another time an exciting cause.

We might also separate, with some advantage, those causes of disease to which the human body is often and necessarily exposed, from those which consist in agencies that are of local or temporary existence only. But without multiplying these artificial distinctions, I shall take occasion to advert to them either when speaking more in detail of particular causes, or when speaking of the disorders they have produced.

In our investigations into the causes of disease, great caution is necessary in order to avoid being misled by individual cases. The circumstances capable of influencing the bodily health are so various—so many of them are apt to be in operation at the same time—and so little power have we of excluding them, one after the other, so as to ascertain the exact efficacy of each—that our observations respecting their relative or their actual effects are open to much fallacy. We endeavour to escape this source of mistake by repeating and multiplying our observations. But it is by tracing diseases as they affect considerable masses of men, placed as nearly as possible under the same external circumstances, that we gain the surest and most satisfactory evidence in respect to the causes of disease. And hence it is that the experience of those medical men who are employed in our fleets and armies is so valuable. Dr. Alison has well remarked that all the circumstances of the whole number of men whose diseases fall under the notice of military and naval practitioners are, in many respects, exactly alike : the men are generally healthy adults in the first instance—the circumstances in which they are placed are thoroughly known to the observer—and indeed are often to a certain degree at his disposal ; they are often suddenly changed also—and changed sometimes as to one portion of the whole mass of individuals, while they remain unchanged as to another portion : so that his opportunities of observation partake in some measure of the nature of experiments, and being made upon a large scale, they are especially interesting and conclusive. In point of fact a great deal has been learned, with absolute certainty, upon this subject.

Hitherto I have simply *enumerated* the principal causes of disease :—but conceiving a bare enumeration of this kind to be of but little use, I shall enquire somewhat more nearly into the nature and mode of operation of several of them *now* : of others I prefer to speak in connexion with the particular diseases to which they give rise.

You will not consider the enquiry superfluous. To know the cause of a disease is sometimes to be able to *cure*, often to be able to *prevent* it. In some cases the cause is beyond our power, but an acquaintance with its nature may teach us how to moderate or to remedy its consequences. There are many diseases also over which medicine has very little control, but the causes of which, when ascertained, may be avoided, or extinguished. Such causes, when they do not happen to be removable by individual efforts, are often susceptible of extinction by the united measures of a community. And for this reason it is very desirable that correct opinions respecting the causes of disease should be widely diffused among the public ;—and there is no way in which information of this kind is so likely to be made generally known, as by communicating it to medical students who are about to scatter themselves in all directions over the face of the land.

I shall proceed, then, in the first place, to the consideration of *heat and cold*, as external agencies capable of producing disease.

Temperature.—The range of atmospheric temperature compatible with human life is very considerable. Its limits are probably just those extremes of heat and cold that belong to the lower strata of the air in the

different parts of the planet on which man is destined to exist. Under the burning sunshine of the tropics, and amid the profound frost of the polar regions, we alike find human dwellers. These different degrees of external temperature impress indeed peculiar physical characters upon those who are subjected to them, but they do not of necessity extinguish life, nor even cause disease. It requires more care, however, to preserve life under intense cold than under intense heat. In some parts of India the temperature ranges for a long time together from 80 to 100, and even 110° of Fahrenheit's thermometer : I believe it sometimes reaches 120°. We can form some estimate of this heat by remembering the oppressive effect of the lowest of these temperatures—that of 80°—to which the thermometer sometimes rises in this country in the hot weather of summer. But these tropical climates are very thickly peopled. In the arctic countries, on the other hand—in the northernmost parts of America for example, where the sun appears above the horizon for a short part of the year only, and where the thermometer sinks to 40 or 50° below zero—we still find inhabitants indeed, but they are few, and thinly scattered. This mainly depends, no doubt, upon the scanty supply of human food in those parts of the world ; but something also is to be ascribed to the depressing influence of extreme cold upon the vital powers. Indeed the deficiency of human food is itself owing to the restraining effect of a low temperature upon organic life. Under a degree of temperature a little greater than that at the equator—or a little less than the lowest around the poles—it seems probable that man would soon perish. And in this fact we have one striking example of the adaptation of external nature to the physical constitution of the human race.

But, *for a short time*—and *under certain circumstances*—man is capable of enduring a very much higher degree of heat than the open and general atmosphere ever attains even in the hottest portions of the earth. Whether he could continue to exist, even for a little while, under a much more intense cold than ever occurs naturally on the surface of the globe, is more questionable.

External effects of heat.—It was long believed that the human body could not be safely exposed, even for a short time, to a degree of heat much exceeding that which is met with in hot climates. This belief, which we now know to have been erroneous, was strengthened by the result of some experiments made by the celebrated Fahrenheit himself, and related by Boerhaave in his Chemistry. Some animals were shut up in a sugar-baker's stove, where the mercury stood at 116°. A sparrow died in less than seven minutes, a cat in rather more than a

quarter of an hour, and a dog in about twenty-eight minutes. The *noxious air* of the stove had probably more to do with the speedy deaths of these animals, than the heat. The truth, upon this subject, may be said to have been discovered by accident. In the years 1760 and 1761, MM. Duhamel and Tillet were appointed to devise some means of destroying an insect which consumed the grain in the province of Angoumais in France. They found that this could be done by subjecting the corn, and the insects contained in it, in an oven, to a degree of heat great enough to kill the insect, but not so great as to hurt the grain. In order to ascertain the precise heat of the oven, they introduced into it a thermometer placed upon the end of a long shovel. The mercury, when the thermometer was withdrawn, was found to indicate a degree of heat considerably above that of boiling water. But M. Tillet was aware that the thermometer had sunk several degrees as it was drawn towards the mouth of the oven. While he was puzzled to invent some way of determining more exactly the actual degree of heat, a girl, who was one of the attendants on the oven, offered to go in, and to mark with a pencil the height at which the mercury stood. And she did enter the oven, and remained there two or three minutes, and then marked the thermometer at 100° of Reaumur, which nearly equals 260° of Fahrenheit. M. Tillet then began to express some anxiety for the safety of the girl, but she assured him that she felt no inconvenience, and remained in the oven ten minutes longer, during which time the mercury reached the 288th degree of Fahrenheit's scale—which denotes 76° of heat above that of water when it boils. When she came out her complexion was considerably heightened, but her respiration was by no means quick or laborious. This experiment was afterwards repeated. Another girl remained in the oven as long as the former had done, at the same temperature, and with the same impunity. Nay, she even breathed, for the space of five minutes, air heated to about 325° of Fahrenheit—or 113° above that of boiling water.

The publication of these facts naturally excited the curiosity of scientific men, and other experiments were soon instituted. Dr. Dobson, of Liverpool, and several other persons with him, shut themselves up in the sweating room of the public hospital there, the air having been heated till the quicksilver stood at 224° of Fahrenheit. They did not experience any oppressive or painful sensation of heat. Dr. Fordyce and Dr. Blagden made some remarkable trials of the same kind. They entered rooms artificially heated to a very high degree, sometimes naked, and sometimes with their clothes on, and bore the

extraordinary temperature of 240°, and even 260°, for a considerable time, with very little inconvenience. In all these experiments it was found that the animal heat, as ascertained by thermometers placed under the tongue, or grasped in the hand, was scarcely increased at all; and the respiration but little affected: but the pulse was very much quickened. The frequency of Dr. Blagden's pulse in one instance was doubled. You may read a detailed account of these experiments in the Philosophical Transactions; but to give you a more lively notion of the degree of heat to which the bodies of these gentlemen were exposed, I may tell you that their watch-chains, and other pieces of metal about them, became so hot that they could scarcely be touched; when they breathed upon the thermometer, the mercury immediately *sunk* several degrees; each act of expiration produced a pleasant feeling of coolness in the nostrils, and they cooled their fingers by breathing upon them. In and by the same heated air which they respired, eggs were roasted quite hard in twenty minutes, and beef-steaks were dressed in thirty-three minutes; and when the air was blown upon the meat by means of bellows, it was sufficiently cooked in thirteen minutes.

It is ascertained, then, beyond all doubt, that the human body is capable of sustaining these very high degrees of temperature, *for a short time*, without detriment.

Facts of this kind may, perhaps, appear to you rather curious than useful. Man is never submitted to any natural heat of the air even approaching towards that to which the authors of the experiments I have been describing voluntarily exposed themselves. But a knowledge of extreme cases always tends to throw light upon those that lie *between* the extremes; and the direct results arrived at in these philosophic enquiries are not barren of practical utility to members of our profession. It is not long ago that a man was found almost dead in an oven: he expired a quarter of an hour after he was taken to one of the Borough hospitals; and an inquest was held upon his body. The newspaper report of the case (which is the only one I have seen) states the temperature of the oven to have been about 120°—a candle was melted by it in half a minute. Now prior to the trials just mentioned exposure to such a degree of heat would have been held a sufficient cause of death. We now know (and it would be discreditable if we could not support our opinion in a court of law, or before a coroner, by a reference to authentic facts) that something else must have concurred in extinguishing life: and, in fact, it turned out that the man was *drunk* when he went into the oven.

But what are the effects upon the human

frame of a high, yet less excessive, temperature of the air?

One very constant effect of heat is that of stimulating the *organic functions* of the body. We have seen that the temporary application of great heat accelerates remarkably the action of the heart: the pulse was uniformly found to be much increased in frequency in the persons who made trials of their powers of endurance in heated rooms. We have evidence to the same purpose in the annual changes that take place in the vegetable kingdom at a given place, the summer renewing its foliage, the winter checking and repressing it; and still more in the superior luxuriance of vegetation in warm climates as compared with cold. And the same observation applies to those functions which animals possess in common with plants. Towards the poles both man and the lower animals are smaller than at the equator. Linnæus remarks that the hares, partridges, and other animals which inhabit the northern climes, are considerably smaller in size than the same species in more southern countries. And Mr. Tooke, in his View of Russia, observes, " As we approach nearer to the north pole, both the animal and vegetable productions of nature become more and more stunted. The ordinary stature of the Samoyedes seldom exceeds four or five feet, and their whole exterior corresponds with their dwarfish size." The bodily stature in hot climates does not, I believe, exceed that which is proper to the temperate zone; but it is notorious that the body grows more rapidly, and that the sexual functions are more early developed, in proportion as we approach the equator: and this is to be attributed to the stimulus of heat acting upon the organic functions, and upon the circulating system in particular.

On the other hand, and in some sort as a contrast with this, we may observe that considerable heat, when applied for some time together, has a sedative or depressing influence upon the *animal functions, i. e.,* upon the nervous system, causing languor and lassitude—want of energy—a disinclination to exertion, both bodily and mental.

Under favourable circumstances, and where due precaution is exercised, it is probable that a very high degree of natural temperature of the atmosphere may be borne with impunity. Sir James M'Grigor informs us (in his account of the passage of the army in 1801 from India to Egypt) that during the march over the sandy desert of Thebes, where the heat was *uniform*, though the thermometer in the soldiers' tents was as high as 118°, the health of the troops was equal to that which they had enjoyed in any former period in India.

But there are some forms of disease which are distinctly traceable to heat as their cause.

The effect of hot weather in promoting the cutaneous perspiration is notorious. By the same influence the hepatic function is rendered more active. Dr. James Johnson first, I think, distinctly pointed out the sympathy or consent that obtains between the liver and the skin, under varying conditions of external warmth. Whatever may be the explanation of the fact, experience has taught us that a high atmospheric temperature, when its operation is continued for some time, has a marked influence upon the liver, increasing the quantity of bile that is secreted, and altering its sensible qualities; and this disturbance of function is not unfrequently followed by inflammation of the gland itself. In this country we witness, almost annually, the effects of a succession of sultry weather, in those attacks of vomiting and diarrhœa which are so common towards the latter end of summer, and in the autumn, especially when the season happens to have been unusually hot, and which result, apparently, from the excessive quantity or the morbid state of the bile. The English cholera (a totally different disorder from that which has of late years been called, most improperly, *the* cholera) is, as you know, so frequent and general in some years, as to be fairly considered and termed an epidemic disease. In tropical climates the same morbific operation of external heat is still more conspicuous; leading not only to violent disorder of the stomach and intestines, with the evacuation of large quantities of vitiated and acrid bile, but also to acute inflammation of the liver going on to suppuration, and the formation of large abscesses. These last diseased conditions are extremely rare in this latitude. The yellow complexions of those who return to England after a long residence in India are to be attributed to that disordered state of the liver, and of its functions, to which such persons are proverbially subject, and which has, in them, been brought on by the influence of a hot atmosphere, operating for a long space of time together. Hepatic affections, acute or chronic, are among the chief diseases to which Europeans, at least, are liable in that climate.

We have here an example of the distinction I wish you to notice between predisposing and exciting causes. The heated atmosphere stimulates unduly the secreting function of the liver. Now a secreting organ is never so apt to be affected by any exciting cause of inflammation as when the process of secretion is going on. This law, which I mention by anticipation, depends, no doubt, on the increased afflux of blood that accompanies the act of secretion. The excessive activity of the hepatic function constitutes thus a predisposition to inflammation of the liver. The hot atmosphere, which

creates this predisposition, holds the place of a predisposing cause in respect to the inflammation that ensues; but the exciting cause is exposure to cold: one of the most common and best ascertained exciting causes of inflammation in general. You are not to imagine that there can be no such thing as exposure to cold in a climate where the temperature of the air is habitually above 80°. Dr. J. Johnson, in his book on Tropical Climates, observes that on the coast of Coromandel the temperature is steady by day, and the nights are hot; but yet, he says, nothing is more common than *exposure to cold* in this place. The European soldier or sailor, after the heat occasioned by his employments in the day, strips off his clothes, and lies opposite a window or port, his shirt wet with perspiration, to enjoy the sea breeze at night. And the same author tells us that the application of cold after or during perspiration commonly produces an attack of hepatitis in some one of its various forms. Now the effect of that kind of exposure here described does not depend upon the *actual* temperature, but upon the *sensation* that is produced, and the sensation depends upon the *relative* temperature; and there can be no doubt that, under the circumstances mentioned by Dr. Johnson, a strong sensation of cold would be occasioned, even by a sea breeze as warm as 80°, or warmer. Changes of temperature seem to be as readily felt at one part of the thermometric scale as at another, and in whichever direction they take place. Dr. Walsh states that while sailing along the coast of Brazil, after having been long accustomed to a temperature of 72°, a strong breeze set in from the sea, and the thermometer fell to 61°; (*i. e.*, to what we should here call temperate); "but," he says, "the sense of cold from the sudden transition of temperature was quite painful. After bearing it for some time shivering on deck, it became intolerable, and we all went below, put on warm clothing, and dreadnoughts,—and again appeared with thick woollen jackets and trowsers, as if we had been entering Baffin's Bay, and not a harbour under one of the tropics."

It is interesting to compare this statement with Dr. Parry's account of a change of temperature at the opposite extreme of the scale, and in the other direction. Having previously said that the thermometer had fallen to 13° below zero in the night of the 21st of October, he goes on thus:—" The wind veering to the south-east on the 24th and 25th, the thermometer gradually rose to 23°. I may possibly incur the charge of affectation in stating that this temperature was much too high to be agreeable to us; but it was nevertheless the fact, that every body felt and complained of the change. We had

often before remarked that considerable alterations of the temperature of the atmosphere are as sensibly felt by the human frame at a very low part of the scale as in the higher. The difference consists only in this, that a change from —40° upwards to about zero is usually a very welcome one; while from zero upwards to the freezing point, as in the instance just alluded to, it becomes, to persons in our situation, rather an inconvenience than otherwise."

Besides the more gradual effects of great heat, direct or indirect, upon the human body, it sometimes operates distinctly as an *exciting* cause, and gives rise to more sudden attacks of illness. Persons who are exposed to the direct beams of a hot sun, especially during any labour or active exercise, are apt to be affected by what is called the sun-stroke, the *coup de soleil*, insolation: they fall down insensible, and often die in a very short time. This disorder is common among troops in long marches in India. It is a complaint of which the cause has long been known by the inhabitants of hot climates. There is a case of it related in the Bible. "And Manasses was her husband, of her tribe and kindred, who died in the barley harvest. For as he stood, overseeing them, and bound sheaves in the field, *the heat came upon his head, and he fell on his bed, and died* in the city of Bethulia."

Pathologists are not agreed respecting the intimate nature of this distemper; nor about the manner in which it destroys life. Some regard it as a sort of apoplexy; and hold that death takes place in the way of coma. But the most approved remedies of apoplexy —bleeding and other evacuations—have not proved successful in relieving it. The natives of India prefer the pouring of cold water upon the head to every other curative measure. Our army surgeons also found that stimulants—rum and water, for instance —answered better than depletion. I have never seen this affection, but I should conjecture that it is more akin to the state we call concussion than to true apoplexy. It would appear that the sun's rays act upon the brain like a shock. The nervous system is suddenly and extensively influenced, and the heart's movements arrested, as in syncope. One of Sir B. Brodie's experiments is in favour of this opinion. He placed a rabbit in a basket in an oven the temperature of which was not more than 150°, and it died in a few minutes without any apparent suffering. The heart was afterwards found distended with blood, on both sides, as after death by asthenia.

Great heat tends also to the production of certain cutaneous diseases: it is said that few Europeans escape, on their first settling in tropical climates, an eruption of pimples, attended with almost intolerable itching and prickling, and lasting for some weeks. It is called in India *the prickly heat.*

Effects of external cold.—Before considering that most prolific source of disease which is familiar to the commonest observation in sudden *transitions* of temperature, let us enquire what are the ascertained effects of extreme cold upon the human frame. Of course I use the term cold in its popular acceptation, as if it were something positive, instead of signifying the mere privation of heat. It is much more convenient to speak of it in this way, and there is no risk of your being misled by my doing so.

Now this inquiry is of more practical interest to us than that which is concerned with the immediate effects of extreme heat. Even in this climate medical men are not unfrequently called upon, in cases of injury or death produced by intense cold, either to remedy the morbid conditions it has caused, or to explain the mode and probability of its operation in extinguishing life.

The effects of cold, as might well be imagined, are in many respects the direct opposites of the effects of heat. When its application is continued, it acts as a sedative upon the organic functions both of animals and of plants. This appears from the shrinking of the external parts: the superficial arteries become unable to transmit the blood in the usual quantity through the integuments. Hence the skin becomes pale, and contracting round the miliary glands and roots of the hair, exhibits a roughness which is compared to that of the skin of a plucked goose, and is technically called *cutis anserina.* By the same contraction of the smaller vessels, and diminished circulation, the extreme and projecting parts are diminished in size. Thus, rings which are tight on the fingers while the body is warm, drop off in cold weather—and even the shoes fall from the feet during extreme exposure. The heart and the whole arterial system becomes weak. I have already, when speaking of the contrasted operation of heat, illustrated the depressing influence of a low atmospheric temperature upon the organic functions, by referring to the dwarfish size of both men and the lower animals, as well as of plants, in cold regions. We have evidence of the same fact in the slow development of the functions, and particularly of the sexual functions, in cold climates as compared with hot; and in the winter torpor of certain animals, which is very analogous with the state of trees and shrubs in that season.

I need not tell you that to judge of the effects of mere coldness of the atmosphere

we must take the case of the atmosphere *at rest*. The air is a bad conductor of caloric, and for that reason, a much lower, as well as a much higher degree of temperature, can be borne when it is in a state of quiescence, than when fresh portions of it are perpetually brought into contact with the surface of the body by currents of air. " With the thermometer," says Captain Parry, " at —55°," (a most fearful degree of cold you will observe, 55° below zero, *i. e.* 87° below the freezing point) " with the thermometer at —55°, and no wind stirring, the hands may remain uncovered for ten minutes or a quarter of an hour without inconvenience ; while with a fresh breeze, and the thermometer nearly as high as zero, few people can keep them exposed so long without considerable pain." And speaking in another place of the cold, when the thermometer was 49° below zero ; 9 or 10°, that is, below the point at which mercury freezes ; he says, " The weather being quite calm, we walked on shore for an hour without inconvenience, the *sensation* of cold depending much more on the degree of wind at the time, than on the absolute temperature of the atmosphere as indicated by the thermometer. In several of the accounts given of those countries, in which an intense degree of natural cold is experienced, some effects are attributed to it which certainly did not come under *our* observation in the course of this winter. The first of these is the dreadful sensation *said to be produced in the lungs*, causing them to feel as if torn asunder when the air is inhaled at a very low temperature. No such sensation was ever experienced by us, though in going from the cabin into the open air, and vice versâ, we were constantly in the habit, for some months, of undergoing a change of from 80° to 100°, and in several instances 120° of temperature, in less than one minute : and what is still more extraordinary, not a single inflammatory complaint (beyond a slight cold, which was cured by common care in a day or two) occurred during this particular period."

But when the cold air is in motion, in other words, when there is wind, so that fresh portions of cold air are brought, in succession, in contact with the surface ; or when it is accompanied with moisture, or occurs under other circumstances favourable to its operation, and to be spoken of more particularly presently, then cold of a much inferior degree of intensity may very speedily occasion partial or total death. By partial death I mean the loss of vitality in certain parts of the body only—the ears, nose, fingers, toes, and feet. The parts thus affected are said to be frost-bitten : and the mode of managing such accidents falling within the province of surgery, I shall con-

fine my remarks almost entirely to the case where general death—death in its full and ordinary meaning, is either brought about, or impending, in consequence of exposure to cold.

One of the earliest effects of extreme cold upon the system at large has been said to be a remarkable and overpowering drowsiness. But I believe you will find that most or all of the persons in whom this torpor has been noticed had not only been exposed to severe cold, but had been using also a great deal of exercise : and perhaps the drowsiness ought to be ascribed, in some measure at least, to that exercise. They who attribute it to the cold alone, explain the comatose state in this way. They say that the chilling of the surface and extremities drives the blood inwards, causes it to accumulate internally, and increases the flow of blood towards the head. One thing, however, is certain, viz. that drowsiness is not a necessary consequence of exposure to severe cold, although it is a very common consequence. Dr. Currie, in his Medical Reports, gives a very interesting account of the shipwreck of an American vessel on the coast of Ireland, by which the greater part of the crew, fourteen in all, were kept for twenty-three hours in a great measure under water, the temperature of the water probably not exceeding 33 or 34° of Fahrenheit : and he states expressly that none of the men were drowsy, and that in no one of the three that perished was death preceded by sleep.

The overpowering tendency of cold when combined with fatigue, and perhaps under certain circumstances of intense cold alone, to induce sleep, was strikingly exemplified in what befel Dr. Solander among the hills of Terra del Fuego. The story, as given in Captain Cook's Voyages, is well known. Sir Joseph Banks and Dr. Solander had been out botanizing. On their return towards the ship, after various hardships, and after having travelled through swamps for a considerable way, the weather, which had been very fine, became gloomy and cold, with sudden blasts of piercing wind, accompanied by snow. Finding it impossible to get back to the ship before the morning, they resolved to push on through another swamp that lay in their way, into the shelter of a wood, where they might build a wigwam and kindle a fire. Mr. Banks (as he was then) undertook to bring up the rear. Dr. Solander, who had more than once crossed the mountains that divide Sweden from Norway, and who well knew that extreme cold, especially when joined with fatigue, produces a torpor and sleepiness that are almost irresistible, conjured the company to keep moving, whatever pain it might cost them, and whatever relief they might be promised

by an inclination to rest. "Whoever *sits down*," said he, "will *sleep*, and whoever *sleeps*, will *wake no more*." Thus at once admonished and alarmed, they set forwards; but they had not gone far before the cold became suddenly so intense as to produce the effects that had been most dreaded. Dr. Solander was the *first* who found the inclination, against which he had warned others, irresistible, and he insisted on being suffered to lie down. Mr. Banks entreated and remonstrated with him in vain: down he lay upon the ground, although it was covered with snow, and it was with much difficulty that his friend kept him from sleeping. Richmond also, one of the black servants, began to linger in the same manner. When he was told that if he did not go on he would in a short time be frozen to death, his answer was that he desired nothing but to lie down and die. The Doctor said he was willing to go on, but that he must first take some sleep; although he had but a short time before told the company that to sleep was to perish. Mr. Banks and the rest found it impossible to carry them, and there being no remedy, they were both suffered to lie down, being partly supported by some bushes, and in a few minutes they fell into a profound sleep. Soon after some of the people who had been sent forward returned with the welcome news, that a fire was kindled about a quarter of a mile on the way. Mr. Banks then endeavoured to wake Dr. Solander, and happily succeeded; but, though he had not slept five minutes, he had almost lost the use of his limbs, and the muscles were so shrunk, that his shoes fell from his feet. He consented to go forward with such assistance as could be given him; but no attempts to relieve poor Richmond were successful. He, together with another black left with him, died.

In many instances, before this complete torpor comes on, intense cold has a curious effect upon the nervous system, blunting the sensations, and confusing the intellect, and giving to the person exposed to it the appearance of one intoxicated. It is very necessary that you should be aware of this, for there is too much reason to believe that poor wretches, who have been picked up by the constables in the streets at night, during periods of hard frost, have been supposed to be drunk, when, in truth, they were only stupefied by the cold. Such a mistake is most likely to be fatal to them: instead of receiving the attention and treatment proper for persons in their condition, they are liable to be laid aside, by themselves, to sleep off their supposed debauch, and the morning finds them corpses. It is not at all improbable that some of you may

be called upon to investigate such cases: and as actual instances are more readily impressed upon the memory than any general description, I will read you a short history illustrative of what I have just been saying, from Captain Parry's Journal.

"John Pearson * * * had his hands severely frostbitten, having unfortunately gone without mittens, and with a musket in his hand. A party of our people, most providentially, found him, although the night was very dark, just as he had fallen down a steep bank of snow, and was beginning to feel that degree of torpor and drowsiness which, if indulged, inevitably proves fatal. When he was brought on board his fingers were quite stiff, and bent into the shape of that part of the musket which he had been carrying: and the frost had so far destroyed the animation in his fingers on one hand, that it was necessary to amputate three of them a short time after."

It is what immediately follows this, that I was desirous of pointing out to your attention.

"The effect which exposure to severe frost has in benumbing the mental as well as the corporeal faculties, was very striking in this man, as well as in two of the young gentlemen who returned after dark, and of whom we were anxious to make enquiries respecting Pearson. When I sent for them into my cabin, they looked wild, and spoke thick and indistinctly, and it was impossible to draw from them a rational answer to any of our questions. After being on board for a short time, the mental faculties appeared gradually to return with the returning circulation; and it was not till then that a looker-on could easily persuade himself that they had not been drinking too freely. To those who have been much accustomed to cold countries, this will be no new remark, but I cannot help thinking (and it is with this view that I speak of it) that many a man may have been punished for intoxication who was only suffering from the benumbing effects of frost; for I have more than once seen our people in a state so exactly resembling that of the most stupid intoxication, that I should certainly have charged them with that offence, had I not been quite sure that no possible means were afforded them on Melville Island to procure any thing stronger than snow-water."

When persons in this state are suffered to sleep, and the operation of the cold continues, they become less and less sensible to external impressions, until death closes the scene.

———

EXPERIMENTS FOR 1839-40.
[Continued from page 156.]

OBS. XII.—In the second and older animal, which was prepared by injection of woorara, and in which, after establishment of artificial breathing, the left ribs were cut quite close to the mesial plane, so as to expose fully the apex in every motion*, after the pericardium was opened, the following results were obtained.

Section 1.—The hard substance (sole leather) weighted with lead, was applied to the heart, and the same result as in the former experiment obtained, viz. a sudden abrupt elevation or jerk upwards of the lead in systole, and a stroke against the stethoscope heard audibly at several yards, and the range of undulation or locomotion of the lead was about half an inch.

Section 2.—On opening the pericardium, the auricles and ventricles were acting as in the former observation, viz. the auricles first after the rest or pause, and the ventricles immediately after the auricles. No auricular sound was detectible. No distinct second sound heard. Heart acting hurriedly, and with varying quickness, but always above the healthy standard.

Section 3.—The motions of the ventricles very conspicuous, and as in last observation, viz. striking diminution of horizontal transverse, and of longitudinal diameters, and increase of transverse vertical diameter in systole, and in diastole increase of the two former diameters, and decrease of the last ; and in systole the apex was raised, as was the whole body of heart, by an elevation of the central longitudinal axis, effected partly by the assumption of a globular form in the previously compressed central inferior surface, and partly by the visible protrusion of the previously depressed central superior surface of the ventricles.

So long as this observation lasted, both auricles seemed to act with equal vivacity; the right auricle being, however, snipped long after the ventricles had ceased, the blood gushed out only when the auricle contracted, and the haemorrhage ceased nearly during the diastole of the auricle.

---

* The former was opened in the same way, and with the same effect.

Section 5.—No other appearances observed in the veins than in the former experiments, viz. a slight diastole with the auricular systole, followed by a systole with auricular diastole.

Section 6.—In neither of the two preceding observations did the auricles and ventricles exactly alternate, but in each, whenever observation was carefully made, the auricular systole immediately preceded the ventricular, and the ventricular diastole preceded the pause or rest, which last was first interrupted by the abrupt auricular contraction.

OBS. XIII. and XIV.—July 15th. *Subjects :*—A donkey (about a twelvemonth old, prepared with woorara. Very little blood lost in opening ; animal not healthy, and weak, so as to be ill able to walk before the operation ; heart acted pretty well), and a dog.

Phenomena.—Donkey : Rhythm of motions ; character of auricular actions ; same of the ventricular ; double friction between heart and pericardium normally ; eccentric impulse felt all over ventricles in systole ; motions of cava. Dog : Normal double frictions of pericardium, with other phenomena.

Section 1.—Rhythm of motions of the auricles and ventricles was as in former experiments. First, auricular systole, then immediately the ventricular systole without interval, and as if it were a continuation by undulation of the former motion.

Section 2.—Then the pause, during which the auricle and ventricle became each distended, and soft and flaccid ; the former sliding its extreme margin downwards on the ventricle, to retract it suddenly again towards the sinus in systole ; and the latter protruding its apex and sides, so as to be enlarged in every direction except that of the transverse vertical diameter, to retract both apex and sides in the following systole, and at the same to rise upwards in its central parts with an impulse.

Section 3.—Before opening pericardium the condition of that sac was carefully observed, and it was noted that while the pericardium remained stationary under all circumstances, the heart suffered much change in shape and size, so that there was in every part, and especially over the auricles, a to-and-fro motion of the cardiac pericardium, on the external layer of that sac ; a friction in one direction in systole, and in the opposite in diastole.

Section 4.—The impulse before observed was obtained by the finger applied to any part of the ventricle in systole.

Section 5.—The cava observed, and a slight action noted, viz. a diastole, followed by a systole, the former with a

wave-like sensation of motion from the heart downwards, and accompanying the auricular systole, and immediately preceding the ventricular.

Section 6.—The separator was introduced into the mitral aperture, and a murmur was heard, but the heart ceased too soon, owing to errors in the process of insufflation, to allow of the experiment being properly followed out.

OBS. XIV.—Same day a dog, small, and perhaps two years old, was poisoned with prussic acid, and then prepared as usual. The heart acted pretty well for nearly half an hour.

Section 1.—The stillness or inertness of the free pericardium, and constant succession of changes of shape and size in the heart, was carefully observed. The heart being, for the size of the animal, much larger than that of a donkey, the experiment was much less troublesome, from that cause as well as from the greater facility of manipulation of a smaller animal.

Every systole of the auricles produced a double friction, viz. one against the external layer of the pericardium, and one against the fundus of the ventricles, or periphery of the auricular orifices ; and every diastole of course produced friction in the opposite directions ; and every systole of ventricle produced friction longitudinally from apex to fundus, and transversely from side to side all round the body of the heart ; while every ventricular diastole included friction in the opposite directions.

Section 2.—The rhythm of the heart's motions was as before, viz., 1st, the auricular systole ; 2dly, immediately thereafter the ventricular, and without marked interval, but as if the latter motion were but a continuation of the former, by a sort of continued undulation ; and 3dly, the pause consisting, first, of auricular diastole, and then including the immediately succeeding ventricular diastole, and interrupted first by the auricular systole.

Section 3.—Cava observed and motion noted, viz. a diastole followed by a systole, the former synchronous with the auricular systole, the latter immediately following.

Section 4.—The subclavian artery laid bare unintentionally for several inches, forming an arch more than two inches in length, and observed to lengthen without straightening in systole of heart, and to shorten slightly, but sensibly, in ventricular diastole.

Section 5.—As in every former distinct observation, the sensation of impulse perceptible on every portion of the ventricular surface. The shortening, rounding, hardening, and elevation of the central longitudinal axis, and increase of the transverse vertical diameter alone of the body of the heart,

easily distinguished ; also the jerking over the orifices, &c. &c.

Section 6.—The auricular systole apparently audible, but the sound not separated by any very distinct interval from the instantly succeeding ventricular sound, which however it preceded rather, and certainly preceded to the senses of touch and hearing together, the hardening and rounding of the ventricle.

Section 7.—In the dog as in the ass, the motions were slow comparatively in the heart, auricles as well as ventricles. The right ventricle first, and afterwards the left ventricle, was penetrated with a slender glass tube, drawn out for a couple of inches at lower end, and the result observed. In systole there was a sudden rise in the tube, and a slight subsidence in diastole. The subsidence was but slight, the greatest not being in the left ventricle more than half an inch, and in the right ventricle still less. The sinking of the blood in the tube in diastole was such as might be caused by a sudden withdrawal of an impulse sufficiently energetic (like that of the systole) to overcome gravitation abruptly, and so as to excite a jet in a tube containing a fluid column, sustained by a constant pressure (such perhaps as might be produced by the venous influx) from below.

Section 8.—In both hearts the right cavities were relieved from distension before complete cessation of action ; and the areas of ventricles, judging by apparent extent of walls opened and spread out, seemed in no degree to differ.

OBS. XV. and XVI.—July 18th. Operated on two donkeys, of from 4 to 8 months old.

Phenomena.—1st donkey. Glass tubes introduced into left auricle and ventricle, and results noted. Normal pericardial frictions observed, and several others.

Phenomena.—2d donkey. Blunt hook and screw successively interposed between mitral valves, with considerable modification of first sound : also spontaneous abnormal sounds ; auricular systolic sound ; results of introduction of glass tubes into heart's cavities. Confirmation of former observations.

Woorara injected in each case. In the first the operation very successful, but in the second, a second dose of two grains required.

In the former much blood lost, owing to an accidental cut made in hastily opening the trachea for artificial breathing.

The heart found acting rapidly, hurriedly, and with a rhythm unfavourable for observation. Second sound not distinct.

The experiments intended were two, viz. stopping the mitral valves by an interposed blunt hook introduced through auricle, or by

a screw-shaped wire similarly admitted. But owing probably to profuse hæmorrhage, the first sound was not sufficiently normal for that experiment, and the second experiment was made, viz. :—

Section 1.—Glass tubes drawn out at one extremity were pushed with a rapid rotatory motion into the auricle and ventricle of left side, and the column of blood observed. That in the auricle gave no satisfactory result, owing to sanguineous exhaustion apparently, and the consequent insufficient distension in diastole, and slight amount of contraction in systole in the auricle. But this much was noted ; viz. that a very short column that filled the drawn-out part was not drawn in in diastole, yet neither was it very strikingly lengthened in systole. The ventricle gave better results, viz. a column rose rapidly by successive stages, rising some lines at each systole, and continuing almost stationary at each succeeding diastole, and at length overflowing the tube, and pouring over in large drops at each systole.

Section 2.—The frictions between the heart and pericardium in systole and diastole of auricles and ventricles ; the tension and jerking motion upwards in systole and softening and subsidence in diastole, of the parietes of the ventricles; the abrupt jerking over the orifices in systole, followed by subsidence in diastole ; the shortening of the diameters lengthwise and transversely in systole ; the immediate succession, as by a continual undulatory motion, of the ventricular systole to that of the auricles ; the sensation of an undulation from fundus to apex on the ventricles ; the dimpling in systole of the left auricle (which only was observed), and the equality post-mortem cordis of the two ventricles ; all those former observations were repeated, and former results confirmed.

Obs. XVI. — Section 1. — The second animal's heart, when exposed, was acting with more regularity than the former, and the blunt hook and screw were successively tried. In each case material modifications of the first sound were repeatedly produced by the interposition of the instrument between the valves in left interior opening ; but the modifications were not constant, and in no case was there any attempt made to impede the right interior valves. This much, however, was noted ; that on several occasions the interposition of the instrument was followed by murmur in the mitral opening with the systole, and by a more obtuse character of first sound, and particularly by a want of sharpness of definition at its commencement. But it is to be added that considerable irregularity existed for the greater part of the time in the sounds, viz. the first sound seemed sometimes, and without apparent cause, more obtuse than

others, and more short and abrupt ; and the second was often wholly wanting, or too indistinct for observation.

Section 2.—Further, there was observed a feeble dull sound, very short and rapid, synchronous with the left auricular systole, and somewhat anterior to the ventricular hardening and uprising, but scarcely separated by any distinct interval from the ventricular sound, and rather continued into it in a manner resembling the apparent passage of the auricular systole into that of the ventricle.

Section 3.—The glass tubes were in this experiment introduced as before with similar results. Nothing striking occurred in that passed into the auricle, but a very short column being obtained, and that nearly stationary : owing probably to the auricle having been penetrated in several places by the hook and screw, so as to suffer escape more readily by the other orifices. But the ventricle gave like results as in the former case, viz. a column rising in systole, stationary in diastole, and at length reaching the upper end so as to overflow. All the previously observed phenomena of the motions of the auricles and ventricles in themselves, and with respect to each other, and with respect to the pericardium, were confirmed in this subject, so that the description of those given under the head of the former experiment of this day, themselves but repetitions of former observations, must be considered to apply to the normal condition, without any important restriction or qualification.

Obs. XVII.—July 26. *Phenomena*—Dog. Distension and hardness of auricles during a torpid, and as it were semi-paralytic state of ventricles — results of a prick in left auricle—proofs of active nature of auricular systole—of negative character of ventricular and auricular diastole—of venous regurgitation during auricular systole—and of equal size of both ventricles, &c. &c. Confirmation of other former observations.

Section 1.—Heart acting regularly, but rather feebly, though large and muscular ; much distended, and on both sides equally. Left ventricle and auricle both much dilated, and the auricle quite tense with blood, so that the appendix could not contract for some time, until a prick was made in it, when a jet was observed coincident with the systole. Some observers thought the jet synchronous with the systole of the ventricle, but on placing the fingers in contact with the sinus venosus and fundus ventriculorum together, it was plain that the jet coincided with the auricular systole, and preceded, by a fraction of a second, the ventricular systole. During the diastole of the auricles a slight shortening of the column, as from diminished impetus from below, occurred ; and again in

auricular systole, a sudden lengthening of the column, to be followed again by a shortening in diastole.

During the systole of the ventricles, immediately succeeding that of the auricles, and without distinct interval, no increase of the jet or column occurred ; and during the diastole of the ventricles, no subsidence, other than the shortening before described, immediately after the auricular systole. During great part of the observation of the jet, the left auricle was tense and hard almost to the finger, and nearly immoveable, and the ventricular action was dull and feeble, and the ventricles themselves were not fully emptied in systole ; the heart appearing to have suffered considerable torpefaction from the poison.

Section 2.—A glass tube was introduced into the left auricle and ventricle in succession, but a clot soon forming, owing to escape of soda solution during the rotatory motion by which the glass was first introduced, no very decided result was obtained.

Section 3.—After the ventricles had become very feeble, and even the left auricle become comparatively inert, some energy of systole was observed in the right sinus, and with each contraction a wave of regurgitation down the vena cava inferior ; viz. a diastole of the vein immediately preceding the ventricular contraction, and coinciding with that of the auricle, and followed by a systole coinciding with ventricular contraction, and auricular diastole. The auricles at no time acted with sufficient energy to promise any result from traction by a string, or to yield distinct sound in systole, owing to extreme distension of the cavities, itself owing apparently to plethora of the vessels, and torpor of the muscular substance, and over rapid and copious supply of blood from the veins.

Section 4.—The ventricles after death seemed not to differ very materially in size, having been cut open before complete death, and allowed to contract.

Section 5.—Several previous observations confirmed on this occasion, viz. as to rhythm of motions cavities, viz. auricles and ventricles respectively exactly together, and the former immediately before the latter, and without distinct interval, but as by continued undulatory motion ; elevation of central parts of ventricles in systole, and subsidence in diastole ; frictions of the pericardium double, viz. both in systole and diastole. &c.

Obs. XVIII. — 30th. *Phenomena.* — Tubes introduced into heart's cavities. Results. Confirmation of former observations as to rhythm, pericardial frictions, changes of shape in the heart, &c. &c. Comparative sizes of ventricles.

Operated on a dog between one and two years old, by prussic acid. Heart acting feebly, with the normal rhythm however ; the cavities considerably dilated.

Section 1.—Glass tubes, containing strong solution of Carb. Sodæ secured, during the introduction, by corks temporarily fixed in the wide end, were introduced by a rapid rotatory motion into the right ventricle, and left ventricle and auricle. Owing apparently to awkwardness in the manipulation, the result was not throughout uniform to the eye, but the general character of what was observed was this. Columns of blood rose into the tubes in every case, and were perceived to overflow in each case with a slight jet in the systole of the cavity penetrated, and a slight subsidence in the diastole.

At one time, for a minute or two, without intermission, the tubes were observed to overflow steadily together, one being in left auricle and the other in the left ventricle ; each having a slight jet or upward undulation in the systole of the cavity containing it. This experiment was comparatively striking, owing to the great difference in colour of the two streams, viz. scarlet, and deep crimson or purple.

During the whole operation nothing occurred suggestive of impulse, except of the impulse upwards of the systoles of cavities, and the slight gravitation or subsidence in diastole ; and this latter, though often very distinct in each tube, was sometimes quite imperceptible in either. No motion downwards in the tubes, such as suction would explain, was observed.

Section 2. — After the observation, the heart was cut out, and the left ventricle appeared rather larger than the right.

Section 3.—The rhythm of the motions of the cavities ; the auricular and ventricular double frictions against each other and the pericardium ; the jerking upwards of the fundus and central parts of the ventricles in systole ; the shortening in systole ; the stationary state of the heart amid all its changes of size and shape ; the subsidence of the central parts and fundus in diastole, &c. were noted to agree with former observations.

Obs. XIX and XX.—August 5. *Subject*—A donkey and a dog. Operated by woorara on a donkey, two or three years old. Operation tedious, owing to strength and resistance of the animal. *Phenomena*—Donkey. Negative character of diastole.

Dog.—Apex cordis threaded, and held tense in the direction of the mesial plane of the subject.—Results : Change of shape and size of the heart in systole and diastole, and visible motions. Glass tube curved, passed into cava inferior. — Results : Columnæ carneæ, and parietes, electrified. — Results : Cavities compared post-mortem, and found equal.

Section 1.—Glass tubes passed into left ventricle at fundus and apex, and in each a co-

lumn rose, and at length overflowed, having a slight subsidence at each diastole, and sudden elevation at each systole, but no well-marked difference between the times of rise and fall in the tubes was detected.

Section 2.—The heart acted for some time with considerable energy, notwithstanding great hæmorrhage, but soon failed after being perforated. The heart was then cut out, while yet contracting vermicularly, and electricity was applied so as to penetrate the columnæ and parietes, but no satisfactory action was obtained. The cavities of the heart had been for some time much distended from loss of irritability before excision.

Obs. XX.—August 5. A terrier dog, stout, though small, was then stunned by a blow on the head and chest ; was rapidly opened, and artificial breathing established.

Section 1.—The apex cordis was then threaded, and at each systole a pull at the cord was observed, followed by relaxation, and the tension and relaxation of the string alternated ; the former coinciding with systole, and the latter with diastole.* At one time the string was kept firmly extended and permanently tense, by holding the hand as far away as the string would allow for a short space, and then maintaining position, but relaxing the hold, so as to allow the string liberty to slide between the fingers when drawn away—and the result was that before the experiment was suspended, an inch or more of the string appeared to have passed between the fingers, one-eighth of an inch at least being pulled through at each systole.

Section 2.—After this observation had been made, and repeated to the satisfaction of all parties, the heart acted still with much vigour, and both sounds were distinctly heard, notwithstanding great loss of blood. Also the diminution of the horizontal transverse, and of the longitudinal diameters, and the increase of the vertical transverse diameter, with sudden bulging upwards of the fundus and central parts, were very plain to the eye in systole, while in diastole the subsidence of the central parts, with sudden increase of the horizontal cross, and of the long diameters, were equally striking. No tilting of the apex as an independent part was noted, nor any other motion than such as might be explained fully by the fixity of the fundus, through the vessels, and the sudden increase of the cross vertical diameter in systole, causing an elevation of the longitudinal central axis, most sensible at the apex or free extremity.

Section 3.—A glass tube was introduced into the cava, with the termination directed towards the diaphragm, when a column of blood rose gradually without any jet until it

* The string was drawn in the line of the longitudinal axis of the heart.

reached the upper end nearly, when it ceased to advance, but continued stationary for some time, and at length sank slowly towards the middle of the tube. No sudden motion either upwards (as ex. gr. by auricular contraction) or downwards (as by diastole suction) was observed. A gradual subsidence in the tube then followed, owing apparently to failure of impulsive force in the moving powers of the venous circulation.

Section 4.—The heart was then cut out while yet contractile, and irritated by electro-magnetism, and by pricking with scalpel, and to the satisfaction of every one present the columnæ carneæ were observed to contract and relax coincidently with the parietes.

Section 5.—The ventricles were equal in capacity to the eye and hand post-mortem cordis.

Obs. XXI. and XXII.—August 8. *Subject*—Two dogs. Two dogs operated on, one a stout terrier, the other a mongrel bitch, both 18 months to 2 years old. *Phenomena*—Second dog. Glass tube introduced into cava. Results variable, with probable causation of fluctuations ; — auricles cease action first ; columnæ carneæ irritated alternately with neighbouring parts of parietes, and results ;—confirmation of former observations respecting the mechanism of heart's action, and the equality of the cavities during life.

In the former animal the operation failed, owing to not having established artificial breathing in time.

In the dog the following results were obtained :—Having been prepared by stunning and tracheotomy, with a view to artificial respiration, the heart was exposed, and found beating with energy, exhibiting the usual motions and sounds.

Section 1.—A curved glass tube introduced into the cava inferior, and immediately a column of blood was observed, which, after ascending some way steadily, and during several beats of the heart, again descended, also steadily and during several beats. After a few minutes, the tube being held upright with care, and the lower opening of the tube being toward the abdomen, and pressure being made on the tube through the parietes of the vein, a column of [blood ascended slowly and steadily to the top of the tube, and poured over at the top. Again, pressure being withdrawn from the cava, fluctuation occurred, viz. irregular ascents and descents of the column, gradually extending, each of them, over several beats of the heart, there being perhaps as many as half a dozen of each to each minute of the time they lasted. At no time was there any sudden elevation or subsidence of the column, such as the auricular systole or ventricular diastole might be supposed to produce, sup-

posing the latter to include suction towards the ventricles. The variations of level observed in the tube could be referred with any probability to nothing obvious, except the play somewhat irregular and convulsive of the right thorax, which was intact, owing to a partial recovery from the stunning blow during the operation, attributable to hæmorrhage and artificial breathing. The tube was then introduced into the cava superior, and a column was observed in the whole length of the narrow part of the tube, and nearly an inch in height, and this column suffered no alteration either in systole or diastole. The shortness of the column in this case was owing obviously to the exhaustion of the vascular system, or insufficiency of blood, and of vascular tension. There was not any respiratory effort during this last observation.

Section 2.—During this last observation (on the cava superior) the unusual appearance was observed of complete quiescence nearly of the auricles, whilst the ventricles continued to act with considerable energy. The early death of the right auricle might be referred to withdrawal of supplies from the cava inferior especially, but that of the left auricle is not easily accounted for, since insufflation was duly persevered in.

Section 3.—The heart was cut out while yet contractile, and the columnæ carneæ of the right ventricle were observed to act accurately with the parietes, whether the stimulus were applied to the former or latter only. The columnæ of the left ventricle were become insensible to stimuli, and the parietes nearly so, before the left was laid open for observation.

Section 4.—The elevation of the central cardiac axis, and especially of its free extremity, the apex cordis, was very conspicuous in systole, and the opposite motions in diastole. Also the flattening and lengthening of the ventricles in diastole, and rounding and shortening in systole, and—after opening the ventricles, the left seemed the larger of the two. The wave-like motion, or sensation as of an undulation from fundus to apex in systole, was very distinct.

[To be continued.]

CASES AND OBSERVATIONS
ILLUSTRATIVE OF THE
MERCURIAL TREATMENT OF SOME
FORMS OF INCIPIENT PHTHISIS
PULMONALIS.

By William Munk, M.D.,
Physician to the Tower Hamlets Dispensary.
[Concluded from p. 163.]

Case I.—April 25, 1838, Mr. J. T. æt. 25. Frequent short and hacking cough, scanty expectoration of a white spumous fluid, hurry of breathing, sensation of heat, and fulness at the upper part of each lung; shooting pains between the shoulders; well-marked hectic; copious morning perspirations'; pulse 100, small, quick, and easily excited; loss of strength and flesh; bowels have a tendency to purging; urine deposits a pinkish sediment. The chest sounds well upon percussion in every part: the ear applied over the scapulæ, and on the anterior surface of the chest as low as the third rib, detects a clear muco-crepitant rhonchus, most abundant on the left side, the natural respiratory murmurs being unmasked over the remainder of the lung. Got wet through in the early part of March: had a rather severe attack in the chest, for which he was cupped between the scapulæ, took aperient medicine, and calomel, with James's powder, at night. By these means he was much relieved, the cough alone remaining; but during the last three weeks, or more, has become rapidly worse, the cough increasing, whilst expectoration, feverishness, emaciation, and shooting pains about the shoulders have made their appearance. Was in perfect health before catching cold. Has been free from any affection of the chest, with the exception of occasional attacks of common catarrh, which, in all previous instances, has quickly subsided. Has lost one sister, æt. 22, from phthisis, and an elder brother is now dying from the same disease.

Hirud. vj. infra sinistram, et iv. infra dextram claviculam.

R Hyd. Chlor. gr. j.; Ext. Hyos. gr. ij.; Pulv. Ipecac. gr. ss.; M. Sextis horis. Milk diet. To be clothed in flannel.

28th. — Increase of fever, greater hurry of breathing, oppression about the chest, and slight viscidity of expectoration.

Hirud. iv. infra sing. clavic.

May 1st.—More comfortable; has a coppery taste in the mouth; gums look spongy, but there is neither tenderness or ptyalism.

4th.—Mercurial action established; cough less frequent; pains of the shoulder gone; expectoration diminished; breathing less hurried. There is increase of fever, and copious perspirations, continuing the whole day.

Pil. j. nocte et mane.

From this time there was a rapid improvement; the mercurial action was maintained for a few days, and allowed to subside gradually. He then took two or three saline aperients, and was placed on sarsaparilla, iodide of potassium, and tincture of hop. The stethoscopic signs vanished, and in three months he was, as he still continues, in the enjoyment of perfect health.

CASE 11. May 8, 1838. Farringdon General Dispensary.—H. S., æt. 26, a porter, caught cold about eight weeks since by getting wet in the feet. Had rigors, which were succeeded by high feverish symptoms, severe cough, soreness over the front of the chest, great difficulty and hurry of breathing, and dull heavy pain of the head. Was attended by a surgeon on the Surrey side of the water; lost blood twice from the arm, and once by cupping below the blade-bones; took medicines, which gave rise to vomiting and purging. Soon got the better of the more severe symptoms, and was enabled to return to his employment; a slight degree of cough and expectoration, however, remaining. These two symptoms have of late increased so rapidly as to induce his master to send him to the Dispensary. The cough is now extremely frequent: expectoration of a greenish-yellow colour; breathing very rapid, especially on exercise; emaciation, loss of appetite, hectic fever, copious morning perspirations, small rapid pulse, and great lassitude. An abundant, very minute, clear mucous ronchus is heard at the top of the right lung; proceeding downwards this became coarser, more scattered, attended with the sibilant, whilst in the lowest portion, and on the left side, the respiratory murmur is unmasked. The resonance on percussion is clear over the whole chest.

Cal. gr. j. ter die.

11th.—Much purged; symptoms rather worse than better; increase of fever, and more restless nights.

Sing. pil. adjic. Opii, gr. ss.

18th.—Purging ceased; mouth sore: in other respects much the same.

Hydr. Chlor. et Opii, aa. gr. j. omni nocte.

22d. — Improved: cough less frequent; expectoration diminishing; breathing less hurried; mouth very sore.

Om. pil. Gargar. è liq. Sodæ Chlorinatæ.

25th.—Expectoration almost gone; cough less frequent; increase of debility, and great emaciation; tongue clean; bowels natural; pulse excessively weak; restless nights. An occasional mucous bubble at the apex of the lung is all that can now be heard.

R Quin. Disulph. gr. j.; Acid. Sulph. dil.; ♏ x.; Tinc. Camph. co. ʒj.; Inf. Cascarilla, ʒxj. M. ter die.

June 15th. — Expectoration ceased, respiration natural; is gradually recovering strength and flesh. Has entirely lost all feverish symptoms, but there remains occasional dry and irritative cough.

℞ Morph. Acet. gr. 1-8th; Aquæ, ʒj. tussi urgente.

℞ Quin. Disulph., Ferri Sulph. aa gr. iss.; Pulv. Cinnam. co. gr. ij. M. ter die.

July 13th.—Perfectly well; has recovered his strength, entirely lost the cough, and every other pulmonary symptom. Auscultation and percussion indicate a healthy state of the thoracic organs.—Discharged.

A prescription was given him for a mixture, containing iodide of potassium, liq. potassæ, and infus. calumbæ.

May 30, 1840.—H. S. continues in good health, and a minute examination of the chest convinces me of the perfectly healthy condition of the lung.

CASE III. Sept. 24, 1838.—Mrs. R., æt. 31, had a severe attack of influenza in July, from which she has never perfectly recovered. After the removal of the more urgent symptoms, she gained a little strength by change of air, wine, tonics, &c., but soon fell back again; the cough, which had never entirely ceased, becoming more and more frequent, is now attended with expectoration, slight in quantity and viscid in quality; rapidity of breathing; sense of tightness about the chest; small, feeble, and rapid pulse; emaciation, and hectic. There is irritability of stomach, thirst, diarrhœa, occasional griping pains, and slight tenderness of the abdomen; tongue rather red towards the edges, and covered in its centre, and at the base, with a layer of dirty mucus: dulness of percussion over the right clavicle. There is heard, anteriorly and posteriorly, in the upper portion of this side of the chest, an occasional sibilant ronchus; more evident than which, and in a great mea-

sure overpowering it, is a subcrepitant. Immediately beneath the clavicle there is slight increase of vocal resonance, and the expiratory murmur is, if any thing, more prolonged than natural.

> Dextro inguini admov. Hirud. vj. et postea cat. commune.

> R Pot. Nit. gr. v.; Sodæ Sesquicarb. gr. x.; Ext. Hyos. gr. ij.; Mist. Acacia, ʒij.; Dec. Cydoniæ, ʒvj. M. ter die.

27th. — Diarrhœa lessened; stools more natural; tenderness diminished; gripings still continue. A large poultice over the whole abdomen.

30th.—Abdominal symptoms much relieved; thirst diminished; tongue cleaner, and less red. Pectoral symptoms worse.

> R Hyd. c. Creta, gr. iij.; Pulv. Ipecac. co. gr. iv.; Cretæ præp. gr. vj. M. sextis horis. Haust. è Mist. Cretæ et Kino si opus sit.

Oct. 2d.—The mercurial has been tolerably well borne; the bowels remain quiet; she complains of sleepless nights, and of oppression about the chest.

> Empl. Cantharidis infra claviculam.

> R Morph. Acet. gr. ⅓; Aq. Rosæ, ʒj.; M. horâ decubitus quotidie sumendum.

7th.—Much the same: sleeps better, but the cough more troublesome; sibilant ronchus gone; subcrepitant more abundant and extensive.

12th. — Slight tenderness of the mouth; symptoms much the same; dulness more marked.

15th.—Soreness of mouth vanished, notwithstanding the regular employment of the powders. Gets gradually worse.

> R Hyd. Chlor. gr. iss.; Pulv. Ipecac. co. gr. v. M. 4ta vel 6ta quaque hora.

21st.—Mouth again slightly affected.
27th.—Mercurial action has been steadily kept up, but without any amelioration; active and passive auscultatory signs increasing; cough constant; breathing very hurried; expectoration presents streaks of a yellow colour. No benefit resulting from the mercurial it was withdrawn. The case went on, gradually increasing, strength failing, pulmonary symptoms becoming daily more distressing; cavities were at length detected, and a severe attack of diarrhœa coming on, she sank rapidly, and died on Dec. 28th.

Case IV. Mar. 26, 1839.—A young woman, æt. 27, had a slight attack of scarlet fever in the latter part of January. She was treated by aperients, and, on account of a pain in the chest, a little difficulty of breathing, and cough, a blister had been applied to the sternum. This gave relief, and feeling herself much better, she returned to her situation; being, however, still troubled with cough. She got gradually worse, the cough becoming more frequent; respiration hurried. She suffered from thirst and considerable heat of skin. On applying for advice she stated that cough and shortness of breath, much increased on the slightest exertion, were the most prominent symptoms. She had occasional pains in the chest, expectoration of a white mucous and spumous fluid, brought up with difficulty, and adhering closely to the sides of the containing vessel. The skin was hot; pulse quick, frequent, and sharp; tongue white. There was considerable thirst, loss of appetite, and slight morning perspirations. She felt extremely weak, and had, within the preceding eight or ten days, rapidly lost flesh. The left scapular ridge was slightly dull; there was here diminution of respiratory murmur, with slight increase of vocal resonance, together with a clear subcrepitant ronchus, which last existed under the left clavicle, as low down as the third intercostal space. The remaining parts of the chest sounded well upon percussion, and the respiratory murmur there, somewhat puerile, was unaccompanied by ronchus of any kind.

> V. S. e brachio ad ʒxij.

> R Antim. Pot. Tart. gr. ss.; Pot. Nit. gr. viij.; Tinct. Opii, ♏ iij.; Aq. ʒj. M. 4ta vel 6ta qq. hor.

28th. — Feverishness diminished; pulse less sharp; thoracic symptoms and physical signs unaltered.
31st.—Pulse rapid, soft, and weak; heat of skin much diminished; copious perspiration; tongue no longer white, but covered at its base with mucus; complains of great debility. No improvement in the condition of the lung.

> R Hyd. Chlor. gr. j.; Ext. Hyos. gr. ij. M. 4tis horis.

April 3d.—Slight feverishness; increased difficulty of expectoration; subcrepitant ronchus more intense.

> Sinst. Scap. admov. Hirud. xij.

4th.—Relieved; dulness of scapular ridge diminished ; gums look spongy.

6th.—Ptyalism established: cough, dyspnœa, and pain of chest diminished; crepitation lessened.

Pil. j. nocte et mane.

9th.—Still improving; mouth keeps very sore; dulness no longer perceptible; subcrepitant ronchus replaced by the mucous; expectoration free, and purulent in appearance.

Om. pil.

12th.—Gradually improving; mouth less sore, expectoration more copious.

Mist. Cascar. comp. ʒiss. ter die.

28th.—Expectoration all but gone; strength and flesh returning; breath no longer hurried.

May 12th. — Thoracic symptoms gone, and physical examination gives a most satisfactory result : experiencing, however, some fulness about the abdomen, and there being torpor of the liver, she had six leeches to the anus, and took, thrice daily, a mixture, containing taraxacum, carb. of soda, tinct. of hop, and sarsaparilla. Under this treatment she lost every symptom of disease, and regained her average weight and usual appearance.

CASE V.—Jan. 19, 1839. S. B., æt. 23, of tall and slender make; guard on one of the northern coaches. Dyspnœa, much increased by exercise ; frequent cough; difficult and scanty expectoration of a clear viscid fluid; occasional pains about, and sense of constriction in, the chest ; heat of skin constant throughout the day, but with a feeling of chilliness towards the evening, and occasional slight perspiration in the morning: in other words, pyrexia, merging into hectic ; pulse small, rapid, somewhat sharp, and easily excited; tongue white ; considerable thirst, anorexia, and emaciation. His present illness has been of five weeks' duration ; was brought on by coming up to town on a cold and very wet night. It commenced as does a common catarrh. This was for a fortnight entirely neglected, he still continuing his journies through the most inclement weather. Finding the indisposition increase, he went to a druggist in one of the provincial towns, who gave him a mixture, consisting, according to his own showing, of oxymel of squills and paregoric. From this he derived

no benefit, and becoming each day worse and worse, was desirous of laying up for a few days. Circumstances prevented his doing so, and he continued his duties until laid up by another cold and wet night. He was prescribed for, and visited at home by a druggist in Whitechapel ; but receiving no benefit, my advice was requested by his brother. The chest sounded well. In the scapular regions of either side, but more particularly on the right, a coarse crepitant ronchus existed; heard also on the anterior of the chest, as low as the fourth rib, but being here less evident than in the back ; respiration was slightly puerile in the lower lobes, but unattended by any abnormal sound.

V. S. e brachio ad ʒviij. vel x.

℞ Hyd. Chlor. gr. iss. ; Ext. Hyos. gr. ij. ; Pulv. Ipecac. gr. j. M. ter die.

21st.—Blood cupped and buffed; felt relief from the bleeding, but, with the exception of diminution in the sharpness of pulse, the feverish symptoms are unaltered.

Iteretur V. S. ad ʒviij.

23d.—Blood slightly buffed; pyrexia diminished; cough; difficulty of breathing; heat and fulness of chest still considerable. Stethoscopic signs unaltered.

C. C. inter. scap. et sang. ʒviij. detrahentur.

24th.—Much relieved by the cupping; constriction of chest and difficulty of breathing lessened; expectoration less difficult.

26th.—Mouth slightly sore; great improvement in all his symptoms; ronchus continues; is, however, coarser, and approximating more in character to a fine mucous.

29th.—Full ptyalism ; cough much diminished ; expectoration more easy and less frequent; the dyspnœa and tightness of chest gone. Pulse 118, small, soft, and very weak.

Pil. j. singulis noctibus.

31st.—Complains now only of slight occasional cough, of the soreness of his mouth, and great debility. Expectorates but little, and the matter brought up presents the characters of declining bronchitis.

Om. Pil. Garg. è liq. Sodæ Chlorin.

℞ Magnes. Sulph. ʒij.; Inf. Rosæ, co. ʒxij. M. sing. auroris.

Feb. 4th. — Improving gradually.

Symptoms and signs of pulmonary lesion diminishing.

Mist. è Quina Acid. Sulph. Dil. et Inf. Lupuli.

In six weeks from this time he was sufficiently well to be again on his coach, the stethoscopic signs having entirely ceased. He so continued until August, when, without any apparent cause, he began to lose flesh and strength. Cough came on, and on the 18th of September, when he called upon me, a cavity was detected in the upper part of the left lung. He died January 6th, 1840,

CASE VI.—March 3d, 1839. Thomas Smith, æt. 30, was attacked on the 18th or 19th of December 1838, with fever, which confined him to his bed for upwards of a month. Suffered a good deal from cough, pain in the chest, and shortness of breath, for the relief of which he had leeches, and subsequently blisters, applied to the front of the chest. He was considerably relieved, but never wholly lost the cough; did not thoroughly recover his strength, but was sufficiently well to return on the 17th of February to his situation, as porter in a Manchester warehouse. He then got wet feet, and increased his cough, which was attended with breathlessness on slight exertion, and a sense of heat within the chest. Getting worse he called on me this morning. The following symptoms were then observed: pallor of countenance, flushing of the cheeks, breathlessness, frequent dry cough, no expectoration, aching pain at the upper part of the chest, worse on the left side. Emaciation and debility, hectic, sleepless and restless nights, tendency to morning perspirations, which are best marked about the chest; pulse 118, small, soft, weak, easily excited; tongue covered at its base with a thickish layer of mucus. There is slight dulness of the left scapular ridge, left clavicle, and two superior ribs. Here the respiratory murmur is more indistinct than on the opposite side; gives the idea of being moister, but neither mucous, crepitant, or sub-crepitant ronchus can be detected. The same character of moisture is impressed upon the respiratory murmur at the apex of the right lung, but is unaccompanied by any other abnormal sign.

7th.—Increase of feverishness, greater
tightness about the chest, coppery taste
in the mouth.

9th.—Ptyalism established; no ame-
lioration of symptoms.

12th.—Much the same. Mercury pro-
ducing a good deal of irritability; diar-
rhœa; stools contain much mucus.

Om. Pulv. Ol. Ricini, ʒss. stat. Cat.
com. abdomini. Mist. è Soda, Hyos. &c.
ut ante.

15th. — Rather more comfortable;
bowels less irritable; stethoscopic signs
and pulmonary symptoms increasing.
The progress of the case from this time
was pretty uniform; dulness on per-
cussion appeared, cavities formed, and
he died in February 1840, from perfo-
ration of the pleura, and consequent
hydro-pneumothorax.

CASE VIII.—Oct. 7th, 1839.—Miss
N., æt. 19. Rapidity and shortness of
breathing, frequent dry cough, dull
heavy pain below the clavicles, great
anxiety of countenance, emaciation,
small, rapid, and rather sharp pulse,
well-marked hectic, slight rigors in the
evening, copious perspirations towards
morning; nights restless, being dis-
turbed by the cough and feverish heat.
The bowels are purged, evacuations
disordered; tongue red at the tip and
edges, but white at the base and centre;
occasional griping in the hypogastric
region, relieved by pressure. Had
measles five weeks since, and towards
their termination was seized with in-
crease of fever, shortness of breath,
soreness beneath the sternum, and
cough. These symptoms after a few
days diminished, but never entirely
ceased, the cough and shortness of
breath remaining. She was able, how-
ever, to get out of doors: soon, how-
ever, became so much worse as to
confine herself to the house, then to
her room, and for the last four days,
since the setting in of diarrhœa, has
kept her bed. Percussion elicits a
clear resonance from every part of the

chest. The results of auscultation are
more of a negative than a positive kind.
The respiratory murmur is almost if
not quite equal in intensity throughout
the whole of the lungs; if any differ-
ence exists, it is in being a little more
feeble in the subclavicular and acromial
regions. There is, however, in these
situations, an alteration of the respira-
tory murmurs; it is as it were moister,
but neither sibilant, sonorous, mucous,
or crepitant ronchi can be detected.

From this period there was a slow,
but gradual improvement. She reco-
vered strength and flesh, entirely lost
the cough, and in December was re-
moved to Ventnor, with directions to
take regularly the following mixture.

R Inf. Sarzæ ad formulam, Doct. O'Beirne, ʒviij., Liq. Taraxaci, ʒiss. Pot. Iod. gr. iv., Tinct. Lupuli, ʒiv. M. Pars quarta primo mane meridie, vespere et nocte sumatur.

This young lady returned to London last May. I then examined her chest, and could discover neither symptom or sign of thoracic lesion.

CASE IX.—Feb. 6th, 1840.—C. H., æt. 24, caught cold in December, which laid him up for a few days. Cough and soreness under the sternum were then his principal sources of complaint. He was getting the better of these, when business called him into Wales; he got fresh cold, which exasperated his cough, and gave rise to other symptoms, which, owing to neglect, have been getting gradually worse. The cough is now almost incessant, unaccompanied by expectoration, save in the morning, when a little clear spumous fluid is brought up. The breath is short, and easily hurried; has no pain within the chest, but is much emaciated, and complains greatly of debility. Well-marked hectic; copious perspiration; pulse 100, weak, but easily excited. The whole of the right lung presents a sibilant and subcrepitant ronchus, the latter most intense in the upper lobe. The right lung is unaffected, and percussion gives a clear sound in all parts of the chest.

R. Hydr. Chlor. gr. j. ter die.   Morph. Acet. gr. 1-8th, urgente tussi.

12th.—Mouth slightly sore; pulmonary symptoms less severe; the ronchi in the inferior lobe notably diminished, but unaltered at the apex.

16th. — Expectoration more free, cough less frequent; stethoscope signs at the apex of the lung unaltered.

21.—Pulmonary symptoms increase rather than diminish; slight increase of vocal resonance at the upper part of the right side, where muco crepitant ronchus is abundant. The lower part of the lung has returned to its healthy state.

Om. Pil. Gar. è liq. Sodæ Chlor.

From this period he got gradually worse; his symptoms were met by palliatives as they arose; cavities formed, and he died on the 26th of June.

    September 26, 1840.

———

OPERATION FOR STRABISMUS.

———

To the Editor of the Medical Gazette.

SIR,

SHOULD the following observations on the dangerous mode of fixing the eyeball by means of a double hook during the operation for strabismus appear to you of sufficient interest to your readers, an early insertion in your valuable periodical will greatly oblige, sir,
          Your obedient servant,
                    A. FRANZ, M.D.

19, Golden Square,
    Sept. 28, 1840.

Ophthalmologists have by experience come to the conclusion, that the operation for cataract performed with the needle restores sight in a less perfect degree than extraction. The reason of this does not so much appear to be that the displaced cataract remains in the eye (for if the operation be performed according to rule, and under the proper indications, it is sooner or later removed from the eye by absorption), but rather that a variety of very delicate textures in the interior of the globe are often severely wounded. This is especially the case in scleronyxis. The wound made with the needle in the conjunctiva is of no consequence; that in the sclerotica heals generally readily and soon (in some cases it causes, however, small swellings, as Soemmering and others have observed); but the lesions caused by the needle to the inner membranes and parts of the eye are like wounds of the membranes of the brain, very dangerous, on account of the inflammation which frequently follows; and if, in addition to those lesions, pressure, stretching, and tearing of these membranes and parts be perpetrated, the danger, as in wounds of the meninges combined with compression or concussion of the brain itself, is not to be foreseen—the consequences may then be so fearful, that the power of vision may not only be still more diminished, but even entirely lost, or the organ itself destroyed.

These facts alluded to are sufficiently well known, and every ophthalmologist, or whoever has carefully observed the progress and result of operations for cataract, will confirm the truth of these remarks. They may, therefore, well form a basis to the following observa-

tions upon fixing the ball of the eye by means of a double hook for the sclerotica, during the operation for strabismus.

Mr. Weiss, who probably has made most of these hooks for fixing the eye, told me that they are generally 1-10th of an inch long, but that by some operators he was ordered to make them even 1-5th of an inch in length.

A horizontal section of the human eye demonstrates, that the thinnest portion of the sclerotica is situated from a distance of one line from the cornea to five lines from this membrane. Dr. Mackenzie, in his Treatise on the Diseases of the Eye, reckons its diameter, in this situation, at scarcely 1-40th of an inch. If we now add to this the tunica albuginea of the muscles of the eye and the conjunctiva, the thickness of these three membranes, in this situation, will certainly amount to not more than to 1-20th of an inch.

If we now compare the length of the hook with the thickness of the above-mentioned three membranes, it follows that it must not only penetrate them, but also wound parts situated within the sclerotica. Injury is therefore always offered to the arachnoid, choroid (consisting of the membrana venosa, membrana Ruyschii, and membrana pigmenti), to the pars non plicata corporis ciliaris, to the hyaloid, and more or less to the cells of the vitreous humour. If the hook is passed into the sclerotica at a distance of less than one line from the cornea, besides these parts, the annulus albidus, the processus ciliares, the orbiculus capsulo-ciliaris, the zonula Zinni, the canalis Petiti, even the capsule, or the lens itself, are wounded and separated in part from their delicate connexions amongst each other. If it is passed through the sclerotica at a distance of more than three lines from the cornea, the retina (consisting of the membrana Jacobi, the membrana nervea, and the membrana vascularis) is wounded. Lastly, if it is passed through the sclerotica in the horizontal equator of the ball, the ciliary nerves and vessels suffer. In this mode of fixing the eye, the lesions are, moreover, of far more importance than in scleronyxis. Firstly, the hook being double, inflicts on each of these textures two wounds, which, in consequence of the formation of the hook, are not, as in scleronyxis, simple and clean incised or punctured wounds, but lacerated and contused. Secondly, to hold the eye with the hook so that it may not slip out, in which case it would scrape just over the centre of the cornea, the ball of the eye must be pressed upon by it; and as, further, the eye is to be drawn towards the opposite canthus by means of the hook, the wounded membranes and parts in the interior of the eye are stretched and torn.

What consequences are we to expect from these, though apparently trifling, yet, when so delicate an organ as the eye is concerned, very important injuries? The consequences will vary according to the parts in the interior of the eye injured, and the extent of injury. To explain them all fully would detain me too long, I will therefore only mention some of the most probable.

Not to take into consideration the pain the employment of the double hooks cause, these are — spasmodic vomiting; ophthalmo- or blepharospasmus; extravasation of blood in the interior of the eye; organic cohesion of the inner membranes, which, in their normal state, are only in contact with each other; varicose metamorphoses of the choroid and corpus ciliare, usually the cause of staphylomata sclerôticæ; interruption of the function of the iris, and the power of internal adaptation of the eye to various distances, thence myopy or presbyopy; opacity of the capsule of the lens (cataracta centralis?); muscæ volitantes, and other defects of the function of the retina; and, lastly, as the squinting eye generally suffers from a weakness of sight, this may be perpetuated or converted into confirmed amblyopy or amaurosis. The one or other of these complaints, consequent upon the application of the double hook, or a complication of several of them, will more readily follow, and, sooner or later, more certainly:—1. the more the ball was not only wounded with the hook, but pressed upon by it, and the membranes and parts in the interior were stretched and torn; 2. the oftener the eye had formerly been diseased, or if there exists a predisposition towards inflammation in the eye; 3. if the patient at the time of operation be in the years of puberty, is, by his occupation, necessitated to exert the eye, suffers from habitual

congestion of the head and eyes or catarrhal or rheumatic affections, or is of strumous or otherwise cachectic constitution.

What I have stated may be sufficient to indicate the dangers awaiting the use of the double hook, and it is really astonishing that even ophthalmologists, not reflecting on the serious consequences it may cause, permit this dangerous instrument to be made use of. Altogether this operation seems to be considered too much in the light of a cosmetic, since, as I have hinted in a paper published in the MED. GAZETTE, Oct. 2d, it is of far greater importance to the patient; and, in the admiration of the novelty and surprising effect of the operation, the delicate structure and functions of the organ appear to be somewhat forgotten. A little reflection upon the anatomy and physiology of the eye would have convinced the advocates for double hooks that the injuries done with them to the inner membranes and parts are by no means indifferent, and that in all operations on the eye, injuries to those textures whose integrity we are justified in concluding to be of the utmost importance to the functions of the organ of vision ought to be avoided.

In operating for strabismus, nothing is more easy than to secure the proper membranes of the eye-ball from all injury, if, instead of a double hook for the sclerotica, we use a simple fine hook for the conjunctiva, and pass it through this membrane and the subjacent cellular tissue in that situation, where it leaves the ball to proceed to the inner canthus. Thus we are perfectly able to hold the ball in a direction forwards, or, if necessary, to draw it outwards, without wounding it in the slightest. The conjunctiva will sometimes be separated a little from its connexion with the sclerotica in the neighbourhood of the hook, but this portion of the conjunctiva may immediately after the operation be removed by a pair of scissors, as it is soon reproduced without any ill consequence whatever. Dieffenbach, as I have stated elsewhere, made use of a double hook for the sclerotica in his first operation only; and then, seeing how unnecessary and even dangerous it was, laid it aside for the simple hook for the conjunctiva. I myself, in my very first operations (*vide* MED. GAZ. April 17th), and in all

subsequent cases, have fixed the eye with a simple hook passed through the conjunctiva, and have found it perfectly to answer the purpose. The hook I employ is made by Weiss, and furnished with a sliding guard, to cover the sharp extremity when passed through the membrane, for security against wounding the cornea in cases of restless children. Latterly I have rejected this hook also, and now use a pair of forceps expressly made for this purpose, and not unlike Assalius's tenaculum, which fully answer the purpose, and have this advantage over the hook, that they can be removed from the conjunctiva with greater facility.

ON UTERINE HÆMORRHAGE.

By FRANCIS ADAMS,
Surgeon.

(For the London Medical Gazette.)

NOTWITHSTANDING the illustration which this subject has received of late from many intelligent writers, and more especially from M. Gendrin, of Paris, it appears to me that there are still many facts to be ascertained respecting the causes of the hæmorrhage, and many points in the plan of treatment by no means satisfactorily determined. For example, we find it generally laid down in the standard works on midwifery, that in all labour cases attended with flooding the discharge of blood proceeds from the separation of a part of the placenta, arising from its abnormal implantation near the mouth of the womb. Upon this point the authority of the "London Practice of Midwifery" is sufficiently precise:—"The proximate cause of puerperal flooding is in all cases the same thing, consisting of a partial separation of the surface of the placenta from that of the uterus." Dr. Burns is equally decided that "if the membranes be still entire, the hæmorrhage proceeds certainly from the detachment of part of the placenta or decidua." Now, without pretending to deny that separation of the placenta is an occasional cause of flooding in labour, I am convinced that it is not the sole nor even the most common cause of it. In continuation of this position I will now call attention to a certain class of labour cases attended with flooding,

which appear to me either not to have been described at all in the common works on midwifery, or, at all events, not to have met with that attention which they deserve in a practical point of view.

About twenty years ago I was called to a woman in labour with her fifth child, and found her much alarmed about herself, as her pains were attended with a considerable discharge of blood. Upon examination, instead of finding the os uteri in its ordinary state, I discovered a large mass of substance, which, from its feel, I took for a portion of the placenta, protruding before the head of the child, which could be felt at the brim of the pelvis. Being then rather a novice in obstetrical cases, I called in a neighbouring practitioner, who happened, however, unfortunately, to be as inexperienced in those matters as myself, and both, after mature consultation, came to the conclusion that it was a case of placenta prævia ; we therefore contemplated being under the necessity of having recourse to forcible delivery, but agreed to wait for some hours, as the woman's strength was not impaired. She continued for the space of about forty-eight hours from the commencement of labour to have occasional pains, attended with gushes of blood, but with some intervals for a few hours, during which there was no hæmorrhage. At last the labour pains set in briskly, and soon changed the aspect of matters : the mass which we took for placenta gradually diminished in size, and slipped over the head of the child, which was delivered without any unusual symptoms. After the birth of the child, being still apprehensive of flooding, I introduced my hand into the uterus, and extracted the placenta, which I found attached, as usual, near the fundus. The woman had a good recovery. After turning over the circumstances of the case in my mind, I concluded that the substance which my coadjutor and I had taken for placenta must have been the os uteri in a swollen state, arising from engorgement of blood, and that the discharge had proceeded from its vessels being in a preternatural state of activity. It is well known that the opening of the os uteri, in ordinary cases of labour, is attended with some discharge of blood : it is natural, therefore, to suppose that the

hæmorrhage should be excessive when, from some cause or other, the vessels of the part are enlarged.

About ten years ago I met with a case similar to the above in all respects, except that the flooding was more alarming than in the case I have related. It terminated, however, favourably, without much interference on my part, or of the midwife who had charge of it.

About three months ago I was called in to see a woman who was reported to be in a very dangerous state from excessive flooding in labour. She was about forty-two years old ; and here it may be proper to mention that, in all the cases I have related, the women were near that age, and had borne several children before. The flooding in this case was such as would have alarmed me much, if I had not ascertained that it proceeded from tumefaction of the os uteri, as described in the two preceding cases. I explained the nature of the case to the female attendant, directing her at the same time to give a few grains of solid opium to the woman, and to apply cold cloths to the hypogastric region. I saw the woman some hours afterwards, and found that the labour pains and the hæmorrhage had been both stopped by the opium. The os tincæ was still swelled to about six times its ordinary thickness. The further progress of the case, as I afterwards ascertained, was this :—About twelve hours from the time when she got the opium the labour pains became strong, and the woman was delivered without much flooding. The placenta came away after the interval of about half an hour.

From the cases which I have related, it is impossible, I think, not to draw the conclusion that abnormal implantation of the placenta is not the sole cause of uterine hæmorrhage in delivery. That cases similar to those which I have described are sometimes taken for placental presentation appears to me extremely probable : indeed, from having fallen into this mistake myself in the first instance, I am the more disposed to believe that others may have committed the same. In fact, the feel of the os uteri, when it is much tumefied, is so different from what it is in its natural state at the commencement of common labours, that a person

not prepared to meet with such a state of the parts, and impressed with the general notion that hæmorrhage in delivery arises invariably from malposition of the placenta, may readily fall into the mistake of taking the swelled mouth of the womb for placenta. I can also believe that tapping of the membranes, as recommended by M. Gendrin, may have the effect of accelerating the progress of labour, and, in this way, of stopping the discharge ; although, from my own experience, I would infer that such a step is uncalled for, as all my cases have terminated favourably by merely observing a cooling regimen, and giving small doses of opium.

I may mention further, that, in the course of my obstetrical practice, I have met with other cases of this description, but none so well marked as those I have related.

Judging from my own observation and experience, I would say that *placenta prævia* must be an extremely rare complication of labour in the rural districts of Scotland. In proof of this I may mention, that after practising in a populous part of the country for upwards of 20 years, during which time I have either attended or been consulted about a great majority of the preternatural cases, I have never met with a single case of abnormal presentation of the placenta, and after making diligent inquiry of the most experienced midwives in the district, I can only learn of one case having occurred in the course in that time. The history of it is instructive. A woman in the eighth month of pregnancy was seized with flooding, for which she consulted a surgeon, who placed her under the charge of a neighbouring midwife. He was several times sent for during ten days or a fortnight, on account of excessive attacks of flooding, preceded and accompanied with slight labour pains, but did not deliver her. At last, upon the occurrence of an excessive discharge of blood, the midwife, upon examination, found the placenta in the vagina before the head. The surgeon was sent for, but did not arrive very soon, and the woman died undelivered. This is the only case of placental presentation which has occurred in a district of a country containing, I should think, not less than 7000 inhabitants, during the space of 20 years. It would

be a curious and instructive fact to ascertain whether it occurs more frequently in towns, and under different circumstances of the inhabitants. According to Mr. Farr, the proportion of deaths from child-bed is 71 per cent. greater in towns than in the country. It would be important to know whether abnormal implantation of the placenta be one of the causes of this greater mortality. For this reason, as well as many others, it would be much to be desired that medical statistics were more cultivated.

I have a few cursory remarks further to make on certain points connected with this subject. It is still generally taught in the common works on midwifery that the placenta is sometimes retained after the birth of the child, in consequence of an irregular contraction of a portion of the uterus around it, so as to form what is called the hour-glass contraction. I have long been of opinion that there is no irregular contraction of a portion of the uterus in this case, but that the os uteri and parts about it have contracted ; that is to say, have returned to their natural dimensions before the placenta has been cast off. It will be invariably found, therefore, when one has occasion to introduce the hand into the uterus several hours after delivery to contract the placenta, that the os uteri has contracted about the latter, so that it appears as if enclosed in a cyst. I was called lately to a case about eight hours after delivery, in which a retention of the placenta had taken place, and the cord had been torn by the efforts of the midwife to deliver it. In introducing my hand I found considerable difficulty in getting it into the uterus, owing to the contraction of the os uteri and the parts adjoining to it, but it was obvious to me that the obstruction was at the entrance into the womb, and not in the intermediate space between the fundus and the os uteri, as it is represented to be by those writers who describe the hour-glass contraction. In short, I am satisfied from my own observation in this and many other cases which have occurred to me, that what is called the hour-glass contraction never does take place.

The excessive discharge of blood which sometimes occurs after delivery would appear to me to arise invariably from the rupture of the small vessels in

the inner membrane of the vagina and os uteri, either occasioned by the expulsion of the child in natural labours, or abrasion produced by the application of instruments. It will be observed, therefore, that whenever much force is used in effecting delivery with the forceps, hæmorrhage never fails to follow, as happened in the case related by Dr. Ehrenreich in the *Medicinische Zeitung*, No. 37. and copied into the 19th No. of the *British and Foreign Medical Review*. In this case a woman, after being 34 hours in labour, was then, on account of narrowness of the pelvis and absence of pains, delivered with the forceps of a living girl, her first child. This was followed by a flooding so excessive that the accoucheur judged it necessary to introduce his hand into the uterus, and apply pressure to the aorta, first with his hand, and afterwards by means of a heavy sand-bag. In two hours after the urgent symptoms subsided, and " *six weeks after* the patient was perfectly well, *with the exception of weakness.*" It may appear presumptuous in me to venture to animadvert upon the practice of another, who is not only more eminent in his profession, but who had superior opportunities of forming a correct judgment of the case in question. But I may be permitted to state that, under similar circumstances, I should have deemed it my duty to wait much longer than Dr. E. did, before having recourse to delivery by instruments. If, instead of delivering at once by the forceps, he had encouraged his patient, and supported her strength by proper means, it can scarcely be doubted that in due time the pains would have returned, and by gradually expanding the perinæum, and moulding the head of the child into a suitable shape, would in this way, at length, have effected the delivery ; and, although this process would, no doubt, have been a tedious and anxious one, both to the practitioner and the patient, it would, in all probability, have been followed by a more satisfactory recovery, so that in the course of *six days* after delivery the woman would have been better than he describes her to have been " *six weeks after.*" I may add, that in the course of my professional practice I have met with many alarming cases of flooding after delivery, but have been fortunate

enough not to lose any of them, although I never have recourse to the active means recommended by Dr. E., and content myself with applying a cloth wet in cold fluid to the abdomen, exposing the woman's parts to cool air, laying her head low, and giving wine and water frequently in small quantities. I have long been convinced that the introduction of the hand into the uterus, in such cases, has more frequently the effect of provoking hæmorrhage than of restraining it.

At the time when I first became connected with the profession it was the established rule of practice, in all severe injuries of the head, to trephine the skull ; and when, as sometimes happened, the patient survived the effects both of the accident and the operation, the surgeon ascribed recovery of his patient from the accident to the operation, and claimed merit to himself and his profession accordingly. Further experience, however, has produced a notable change of opinion on this subject, and it is now generally believed that the great number of deaths which formerly occurred after such accidents is to be ascribed to the *nimia medici diligentia*. And perhaps the time is not far distant when it will be generally admitted that a less vigorous plan of treatment in uterine hæmorrhage is much more effectual in saving life than that which is now pursued—namely, the practice of introducing the hand into the uterus, stimulating its abraded surface, compressing the great blood-vessels of the abdomen, and laying heavy weights on the belly.

Banchory, Aberdeenshire, Oct. 10, 1840.

<div style="text-align:center">

ON THE
USE OF GUAIACUM IN CYNANCHE TONSILLARIS.

</div>

To the Editor of the Medical Gazette.

Sir,

I beg leave to send you a few cases of cynanche tonsillaris, treated by guaiacum, for insertion in your valuable journal, if you deem them worthy of a place in its columns. – I am, sir,

Your obedient servant,
Joseph Bell, Surgeon.
Barrhead, October 10, 1840.

Case I.—Mrs. T. (Nov. 18, 1838), a stout healthy lady, æt. 23 years, of dark complexion : complains of severe

pain of throat, and difficulty of deglutition, which is attended with severe pain, headache, rigors ; pulse 108; surface hot ; face flushed ; tonsil of right side much swollen, of a deep crimson colour, and on its anterior surface, there is a small greyish looking patch of lymph ; velum pendulum palati red, swollen ; left tonsil also slightly swollen and red, but pain is chiefly referred to right side ; tongue white and furred ; complaints commenced yesterday, when she took an ounce of castor oil, which operated freely ; has had several similar attacks, which always ended in suppuration.

> Habt. Tr. Guaiac. ʒij. ; Mucil. G. Arab., Syrup. Simpl., aa. ʒij. ; Aq. Cinnamom., Aq. Puræ., aa. ʒiv. M. et solut. sunat. ʒij. 6ta. q.q. hor.

19th.— Headache gone; pain of throat much relieved ; pain on swallowing very slight ; pulse 90; skin moist ; tonsils less swollen, and redness nearly gone, tongue very white ; bowels freely moved.

> Contin. medicamenta.

20th.—Has no pain in throat to day; can swallow with perfect ease; feels quite well ; swelling of tonsils almost gone ; pulse 72.

> Intermit. medicam. sed utat. Gargarism. Boracis.

CASE II.—Jan. 6th 1840. Miss M'A., æt. 21, of a weakly habit : complains of severe pain of throat, rendering deglutition excessively painful and difficult : face flushed; headache; right tonsil very much enlarged, and of a fiery red appearance ; velum pendulum palati and uvula in a similar state ; tongue covered with a deep dirty white fur; pulse 120; rigors ; bowels irregular ; was seized with pain of throat yesterday afternoon ; left tonsil suppurated about two months since. Ordered to have the same mixture as prescribed in last case.

7th. — Pain of throat and difficulty of swallowing gone ; redness and swelling of tonsil and fauces nearly gone ; headache relieved ; pulse 72. Cont. bowels freely moved.

8th.—Free from complaint.

> Intermit medicament.

CASE III.—Jan. 25th 1839. David M'C., æt. 30, a stout active man : complains of severe pain of throat ; both tonsils exceedingly red, and very much swollen, so much so that they almost meet ; uvula of a similar colour, and

swollen ; cannot swallow any thing solid, and fluids cause excessive pain ; pulse 106 ; skin very hot ; bowels have been opened by sulph. magnes. ; has been ill for the last three days.

> Habt. Mistur. Guaiaci, ʒij. 4ta. q.q. h.

26th.—Feels greatly relieved of his pains ; has been able to take some breakfast ; tonsils much less red and swollen; pulse 80 ; bowels freely moved ; perspired freely during night. Cont.

27th.— Feels quite well ; can swallow with great ease ; tonsils have nearly resumed their natural appearance.

> Intermit medicament.

CASE IV. — Feb. 9, 1839. Mrs. M'Nab, æt. 27 years, fair complexion, full habit, complains of severe pain of throat ; countenance flushed ; eyes suffused ; violent headache ; skin hot ; tongue white, deeply furred, yellow streak in centre ; both tonsils highly inflamed ; velum pendulum and uvula in a similar condition ; deglutition accompanied with very acute pain ; back of pharynx covered with a dirty yellow layer of lymph ; rigors ; pulse 110 ; bowels freely moved yesterday by infus. sennæ. Was seized yesterday, after exposure to cold. Ordered the guaiac. mixture as in the other cases.

10th. — No complaint ; feels quite well, although left tonsil is still a little enlarged, but is now pale. Cont.

11th.—Continues well.

CASE V. — July 7th 1839. John Buchannan, æt. 25, dark complexion, of a full habit : complains of difficulty of swallowing, and pain in right side of throat ; has not been able to take any food for the last twelve hours from pain of throat ; rigors ; right tonsil very much enlarged, and of a deep red colour ; uvula in a similar condition ; pulse 114 ; tongue covered with a dirty white fur ; bowels open ; has been ill for three days.

Was ordered to follow the same treatment as the other cases.

8th.—Pain of throat gone ; can swallow with freedom ; inflammatory appearance of tonsil nearly gone ; pulse 70 ; bowels freely opened. Cont.

CASE VI. — March 18, 1840. M. M'Farlane, æt. 45 years, a weakly man : complains of inability to swallow from severe pain of throat ; both tonsils highly inflamed ; as is also uvula ; tongue white, furred ; pulse 120 ; great

restlessness from pain of the throat; has been ill for nearly three days.

To have the guaiac. mixture, as ordered in the preceding cases.

19th.—Had great difficulty to swallow medicine at first, but can now take some food, as complaints are nearly gone. Cont.

20th.—Free from complaints.

Intermit medicament.

The above six cases are selected at random from about forty cases, all of similar import, except two, in which suppuration took place, although the medicine was assiduously administered. I was first led to use the remedy from the recommendation of Professor Hannay, Glasgow, and I have found it highly beneficial in the speedy removal of this very troublesome complaint. The two cases referred to were of many days duration when the guaiacum was given, and this may account for its failure in these instances. I have not the slightest doubt but that, if timely administered, it will, in 99 cases out of 100, cut short the affection in question.

DE QUIBUSDAM GENITALIUM MASCULORUM PROPRIETATIBUS.

[*For the Medical Gazette.*]

UBI jam thalamo se composuit homo viribus integer, suosque sopor occupavit artus, membrum tumet genitale. Hoc non raro, sed semper, haud sparsim, sed toto evenit generi marium adultorum.

Hæc veretri inflatio, corpore vigenti, somno incipit obrepente: somno gradatim cessante desinit.

Plerique, cum nox primò somnum conciliet, altùm dormientes hujusce tumoris haud conscii sunt. Nocte autem adultâ, quum vesica urinis repleatur, expergiscuntur matulam quæsituri, dolorem cystidis distensæ evacuatione sedaturi. Hoc ipso tempore sentitur erectio virgæ.

Erigitur autem membrum primis horis; nam si clamor subitus de suo "balmy sleep," virum expergefecisset, illo etiam tempore percipiatur inflatio.

Hæc in impuberibus varissimè, in adultis, sani corporis, semper notatur. Sani, dico, corporis; scilicet febriculâ, seu mærore corpus, aut animum oppri-

mente, interrumpitur somnus, flaccet virga. Veretri durities distensi ad virorum valetudinem coæquatur. Hæc autem erectio medicorum et physiologorum lucubrationibus est dignissima.

Medicus haud rarò, si arte exercendâ multum occupatus sit, miserum conspicit, qui sese amoris impotentem lamentatur.

Sed imbecillitas hæcce non semper a corpore; frequenter ab animo derivatur.

Ad morbum idcirco sublevandum discrimine acuto opus est. Mentula noctu distensa diagnosin reddet facilem.

Perfectâ erectione structura genitalis, quo ad partem corpoream, efficax et naturalis arguitur.

Medicus, hoc intelligens, animi morbum haud corporis languorem ægro miserabili detegit; et modis subdolis ad mentem respicientibus, virum ad vires revocabit.

Hæc genitalium, somno artus solvente, vivacitas alios propter ægrotos magni est æstimanda.

Sæpè enim medico flentes queruntur ægri de *seminis emissione*, noctu turbante, somniis aut lascivis aut usitatis.

Hæc verò profluvia, viris a venere alienis, haud morbo sed naturæ referenda sunt. Idem stimulus, eadem irritabilitas mentulam producunt, semen expellunt.

Hæc evacuatio, motuum consecutorum ultimus, genitalium evincit vigorem; nisi frequentissimè continget; frequentissima morbum indicat asthenicum.

Mihi hæc perpendenti, videlicet veretri duritiem, seminis somno profluvium, mirabilis videtur consensus legis naturæ præceptis cum moralibus.

Lex enim est physica organorum animalium vires usû firmatas, etiam auctas esse; desuetudine infractas. Aures, oculi, nasus, lingua, tactus—ad quantam sensûs ἀκρίβειαν usû perveniant!

Quanta sensuum hebetudo, si torpescant otio!

Cataracta oculi potentiæ, quâ cernit, se opponens, si multos annos inveteraverit, retina vim perceptivam perdet.

Usus crurum aut brachiorum si pro tempore cesset, fient membra tenuiora. Musculi more insolito exercitati quantum adipiscantur magnitudinem!

En athletarum corpora! Ex pede, dicitur, Herculem. Ex musculo bicipite Crib, Molyneux, Gully, M.P.

Talis est lex physica. Precepta verò

moralitatis Christianæ huic legi obstare *videntur*, castitatem exigentes perfectam.

Quæ, si ritè hæc serventur jussa, multis cœlibibus per menses, per annos, sit duratura.

Quid ergo? Morum puritas partium genitalium vires minuit? Haudquaquam. Quippe potentia hisce nocturnis mentæ inflationibus mirum in modum conservatur. Naturæ et sanctitatis admiranda congruitas!

Multi prætereà mœchi, obtentum vitiis quærentes, concubii necessitatem asseverant. Si castè vivant, plethorâ seminali, sic aiunt, corripientur; et ægritudine seu morte prematurâ virtutis stultitiam monstrabunt.

Falsa! Ipsæ, enim, emissiones, naturæ mandato, plethoram, seu universalem, seu genitalium, præveniunt.

Sic mandata Christi et natura corporis consentiunt. Dum homines lascivi culpam à se haud amoveant ; casti infirmitatis timorem hilariter objiciant. Nec poetâ sceptico concordent, turpiter blaterante—

" Tantum religio potuit suadere *malorum*."

ROBERTUS HULL. M.D.

Norvici,
Octobris 1840.

REPORTS OF CASES,

By H. M. HUGHES, M.D.

Assistant Physician to Guy's Hospital, and Physician to the Surrey Dispensary.

[*For the Medical Gazette.*]

Pneumonia.—Though the occasional existence of a latent form of the complaint cannot be doubted, there are few diseases the characters of which are usually more distinctly marked than pneumonia. The general symptoms, and the physical signs; the pungent heat of skin, to which attention has been recently called by Dr. Addison; the viscid rusty expectoration ; the short hacking cough, occurring especially after each attempt at deep inspiration; the peculiar crepitating rattle ; the defined dulness on percussion, and the resonance of voice over the affected part, are sufficient to distinguish its early stages from all other diseases with which it is liable to be confounded. I have, however, not unfrequently observed that young and inexperienced

auscultators decide upon the existence of pneumonia from the simple fact of hearing a crepitating rattle, of whatever form or quality ; and as this rattle, under some of its phases, exists in œdema of the lung, in inflammation of the minute bronchial tubes, and in what is called pulmonary apoplexy, as well as in the early and receding stages of pneumonia, it has been supposed by some that it cannot be regarded as characteristic or pathognomonic of that disease. There are others, accurate observers, who consider that the crepitating rattle of pneumonia is peculiar, and distinguishable from that accompanying all other affections of the chest. Whether a previous stage can be recognised by a local puerile respiration, as some authors believe, or whether the presence of the pulmonary congestion, which at least sometimes precedes inflammation, may be ascertained by the " humid ronchus with continuous bubbles," as stated by M. Fournet – or whether there are any characters in the rattles which are sufficient to distinguish the crepitation of advancing from that of receding pneumonia, as has also been asserted by that gentleman—my recent experience has not enabled me to form a decided opinion ; but observation induces me to believe that a small, fine, equable, and dry crepitation, occurring in puffs towards the termination of the inspiratory movement, is certainly characteristic if not pathognomonic of an early stage of the disease.

Of all complaints of the chest, none, with the exception of pleuritis, have appeared to me to be so entirely under the control of remedies, when occurring in persons of good constitution, as pneumonia. As I have generally found the ordinary plan of treatment by bleeding, calomel, and antimony, to be effectual in subduing the disease, and as I have sometimes seen it recur more than once after its temporary reduction, until the system has been brought under the influence of mercury, after which it has rapidly and entirely disappeared, I have never yet treated a case of pneumonia by large doses of antimony alone, though I believe that there are instances, particularly in children, in which such treatment may be desirable. Not having myself, however, met with them, and already possessing means of subduing

the disease, the efficacy of which had, I believed, been abundantly proved, I have not felt justified in trying experiments of other methods of cure in an affection the character of which is so important as, in its result, to involve the life or death of the individual.

The preceding remarks upon the usually remediable nature of pneumonia, and the efficacy of the means ordinarily adopted for its cure, may appear singularly inconsistent with the fact that the three cases noted in the table formerly published all terminated fatally. This inconsistency will, I think, entirely disappear, when the circumstances connected with these three cases are attentively considered. They were the following:—

1st.—A child, aged five months, who had been ill for three or four days before I saw it, was at that time blanched from loss of blood, and other active treatment, and had a sloughing blister upon the sternum: the respiration was extremely frequent, and the pulse a mere flutter. Stimulants were immediately administered, but it died the next or succeeding day. This, had it been sufficiently early, might probably have been a fair case for the exhibition of antimony. No examination was allowed.

2d.—A man, aged 60, by occupation a carter, of very intemperate habits, who, according to his wife's statements, had taken very little solid food for some years, and had lived almost entirely upon porter and spirits. When visited he was labouring under subacute pneumonia of the left side, which, as indicated by the stethoscopic signs, appeared to be reduced by the mild antiphologistic measures adopted for his relief. The natural sound on percussion of the part returned; the resonance of the voice ceased; the febrile excitement subsided; the cough was far from frequent or troublesome, and he had no hectic; but he took no food, and having entirely lost his relish for his formerly favourite beverge, he lingered on for six weeks or two months, and seemed ultimately to die, not so much from the direct consequences of his primary disease as from exhaustion, resulting from his incapability of taking sufficient support. No examination was allowed.

3d.—C. B. aged 18, a thin youth, of light complexion, whose ordinary occupation was in a gas-factory, took scarlatina from his younger brothers, who passed through the disease without danger, and almost without inconvenience. He was not seriously ill, and was confined to his bed only one day, Sept. 24th, after which, the rash not having disappeared, he returned to his work, and continued it till the evening of the 28th, up to which time he drank freely of cold water, as was his custom while heated by his occupation. On that night he complained of feeling very ill, and of severe pain in his back, right side, and scrobiculus cordis, and subsequently of cough and dyspnœa. He was seen by a surgeon, who bled him twice, on Sept. 29th, to about 16 ounces; and on Sept. 30th, to 12 ounces, and prescribed such medicines as he thought fit. On Oct. 1st he was admitted a patient of the Surrey Dispensary, under my care. I found him lying on his back, with his shoulders raised; a flushed turgid face, and anxious countenance; a hot and pungent skin; a red dry tongue; his respiration 48 in the minute, and very laborious; his pulse 140, fluid and compressible. He had a frequent cough, with an abundant thick and viscid, yellow, muco-purulent expectoration. He had passed in the previous twenty-four hours between two and three pints of dark purple-coloured urine, with some coagula of blood. His distress was too great, and he was altogether far too ill, to render a minute stethoscopic examination of the chest either necessary or justifiable, but dulness on percussion was sufficiently evident on the right side of the chest, below the mammary region, together with increased resonance of the voice, and distance of the bronchial rattles. The same was observed on the lower part of the left side posteriorly. The upper part of the chest sounded well on percussion; but here, as in every part of both lungs, was heard an intense mucous rattle. His pain he referred to the loins, and inferior part of the right side of the thorax. On the whole he presented one of the most acute, extensive, and unpromising cases of recent disease, that I had ever witnessed. Ordered

C.C. lumbis ad ℥xii.; et lateri dextro ad ℥vi. Descendat in balneum callid. et postea applicetr. Cataplasma Lini lumbis. ℞ Pulv. Jalap. gr. xii.; Hydrarg. Chlorid. gr. iij. st. sumend. ℞ An-

11 P.M. Had had a comfortable sleep, but was no better, and he expired at 1 P.M. the next day, being perfectly conscious, and without important change till within half an hour of his end.

Inspectio cadaveris twenty-seven hours after death. — Externally there was evidently considerable enlargement of the right side of the chest, with great dulness on percussion. The head was not opened. Chest: on removing the sternum there was exposed, rather to the right of the median line in the lowest part of the mediastinum, a small defined abscess, entirely unconnected with the inflam-

mation affecting other parts, and containing about ℥ss. of healthy pus. The right pleura contained about two quarts of thick fœtid sero-purulent fluid. The serous membrane itself, and particularly that investing the lung, was covered with a thick layer of firm yellow lymph, arranged in slightly curved almost parallel lines, the spaces intervening between which were comparatively free from effusion. The right lung was compressed to one-third or one-fourth of its natural size, but was otherwise entirely free from disease, even close to the inflamed serous membrane, with the exception of the lining of the bronchial tubes, which was of an intensely red colour from injection, and nearly filled with purulent mucus, but apparently neither softened nor thickened. On the left side the pleura was adherent from very recently effused false membrane, and red from numerous small vessels. The entire lower lobe of this lung was in a state of red hepatization from pneumonia. The upper lobe, excepting at its lower and posterior portion, where it partook of the disease of the inferior lobe, was healthy; but here, as on the right side, the bronchial membrane was of a light crimson hue from injection. The pericardium was partially adherent by recent lymph to the anterior mediastinum; internally it was healthy. The heart was free from the appearance of disease, with the exception of a slight roseate tint of a portion of the lining of the left ventricle. Abdomen : the liver, stomach, spleen, and pancreas, were healthy, and no appearance of disease was presented by the intestines. The left kidney was healthy ; the right was large, its surface was irregular, and its cortical substance rather softer than natural ; the tubular portion was of a deep purple colour, hard, and full of blood : its tubules were particularly large and distinct, and the sides of one of its calyces were adherent by the intervention of recent but distinct cellular membrane.

The preceding case presented one of the most severe and acute attacks of disease I have ever witnessed, either in my own practice or that of others, whether public or private. When first visited by me, the patient was suffering from intense bronchitis, from pleuritis of the right side, from a small amount of pneumonia in the left, and

from rather profuse hæmaturia ; from all of which, to my very great surprise, and with a gratification perhaps rarely experienced, except in similar circumstances, I saw him in a few days rapidly recovering. The hæmaturia had ceased, the cough had much decreased, both in frequency and violence, and all pain had been removed ; the skin had become soft and moist, and the pulse was reduced considerably in number. To this unexpected and pleasing progress I believe the hot bath greatly contributed, by inducing determination to the skin, and a copious perspiration. But, while thus favourably advancing, the patient needlessly and carelessly exposed himself to cold by throwing off the bed-clothes, and sitting up without proper covering. Most of his former complaints immediately returned with increased violence; the pneumonia of the left side extended considerably ; the effusion in the right side rapidly increased, and he died in a few days after the relapse. Though I supposed pneumonia to a small amount existed when I first saw him, as indicated by the pungent heat of the skin, and the dulness under the left scapula, I believed that it was not then nearly equal in extent to that found after death. My reason for this opinion was the absence of the physical signs of the affection in the greater portion of that part of the lung in which it was afterwards found, the evidently recent character of the disease, and the obviously different stages of the inflammation of the pleura in the two sides. Subsequently to the relapse no efficient examination of the chest could be made, and the progress of the inflammation, therefore, could not be then accurately noted, independently of which the weakness of the voice, and the loud bronchial rattles existing throughout the lungs, would have prevented the correct appreciation of two of the most important of the physical indications of the presence of pneumonia, even had a minute examination been practicable. The cadaveric inspection abundantly proved the severity of the complicated disease ; and the case is a strong illustration of the care that is required to avoid exposure to cold during the progress of acute affections of the skin, on the one hand, and severe internal inflammations on the other.

SOME REMARKS
ON THE
PLACENTAL TUFTS DESCRIBED BY
WEBER;

AND ON THEIR DISTRIBUTION AND SUP-
POSED FUNCTIONS.

By J. KNOX, M.D.

[*For the London Medical Gazette.*]

WHEN Dr. Lee published, in the Phi-
losophical Transactions, the result of
his highly interesting inquiries into
the mode of connection between the
human placenta and uterus, a result
supposed to be unfavourable to the
accuracy of the views and dissections
of the greatest anatomist and physio-
logist that ever lived, I took the ear-
liest opportunity of returning to an in-
quiry which had repeatedly engaged my
anxious attention ; and seized with
eagerness the first opportunity which
occurred of re-examining the struc-
ture in question.

I need not here recapitulate what were
supposed by most persons to have been
Mr. Hunter's views on these interesting
points ; his celebrated memoir must be
familiar to all physiologists. Neither
does it follow that the generally received
notions as to what were the great
anatomist's views, may, after all, be the
accurate expression of what he meant.
Mr. Hunter's occupations were too va-
ried and too serious to permit of his
giving to the result of his researches,
when committed to paper, that plea-
sant, flippant, clear (being shallow),
off-hand style, so delightfully prevalent
in the present day. It is sufficient for
me to say here, that Dr. Lee's dissec-
tions and observations are supposed by
himself, and by many others, to be ad-
verse to those of Mr. Hunter. In this
opinion I, for my own part, did not
altogether agree. Admitting, however,
that the real nature of the connection
between the placenta and uterus was
still involved in great obscurity, of
two facts, and of the certainty of these,
I had long made up my mind ; first,
that minute vessels containing coloured
blood do really at all times pass from
the uterus to the placenta, or *vice versâ*,
but that these vessels had never been
fairly traced to their origins ; and se-
condly, that the notion entertained by
many that the uterine veins actually
enter the substance of the placenta, or

at all events reach its surface, together
with that other idea that they termi-
nate or commence by open mouths on
the inner surface of the uterus, and
that they there take up the blood poured
into some intermediate cavities, or forced
into them by the placenta through the
placento-uterine decidua, was a state-
ment, according to my humble belief,
at variance with every thing I had
seen of these textures, and with all
that I believed to be sound in anatomy
and physiology.

I am particularly anxious not to be
misunderstood, or thought dogmatical ;
and from having had no opportunity of
examining Mr. Hunter's preparations
with sufficient care and attention, I
felt that although many doubts arose
in my mind as to the accuracy of his
views, I was scarcely entitled to speak
positively respecting the extent to
which his dissections bore out his
theory. Finally, I found it impossible
to reconcile the language of his memoir
with what I had myself seen on dis-
section.

The first opportunity I had afforded
me of examining the impregnated ute-
rus, with the placenta adhering and un-
disturbed, was not a favourable one ;
but it satisfied me of this, that minute
vessels of some kind or other do pass
from the placenta to the uterus, and
that the mode of the commencement of
the uterine veins or sinuses on that sur-
face of the uterus to which the placenta
adheres had not been fairly described :
this dissection and a subsequent one
agreed to a certain extent with Dr.
Lee's views ; but notwithstanding this
uniformity, with which at any other
time I would have felt highly gratified,
it was impossible for me to persuade
myself that we had seen the whole
truth ; indeed, I preferred Mr. Hunter's
views, although they seemed in part to
be against the evidence of my own
senses. To suppose, for example, with
Mr. Hunter, that the uterine veins pass
through the decidua to the surface of
the placenta, and that the uterine
arteries, besides having this course,
likewise terminate by visible mouths
in these veins, or in the pretended cells
of the placenta, were statements quite
at variance with every dissection I had
made. But it could not escape obser-
vation that Mr. Hunter, without ven-
turing precisely to define its nature,
had described " a fine spongy sub-

stance visible on the surface of the placenta, the interstices of which were filled with a yellow injection which had been thrown into the veins of the uterus." These are Mr. Hunter's own words, in his celebrated memoir on the "Structure of the Placenta." He says, moreover, that the veins of the uterus (and arteries too, if I rightly understand him,) terminate upon these "fine spongy masses."

The next opportunity of examining the impregnated uterus and placenta *in situ* I obtained through the kindness of my most esteemed friend and former pupil and assistant, Dr. John Reid. With a liberality worthy of Dr. Lee himself, he allowed me to examine, for nearly an hour, a large portion of the uterus, with the placenta adhering, of a person who had died of an acute disease, and undelivered.

When I first saw it (March, 1839), it had been laid open, and had been repeatedly handled and examined by others. The light was unfavourable for minute dissections, and it was out of my power to apply glasses of a higher magnifying power than a common pocket lens. What I then saw I shall now record, premising that, as the appearances were new to me, however strongly they recalled to my mind some of Mr. Hunter's phraseology, I informed my morning class that I should at the lecture of that or of next evening explain to them certain very interesting appearances I had just observed respecting the structure of the placenta, and its mode of connection with the uterus; but as I had some recollection that one or two German anatomists had recently made this very subject their peculiar study, of whose labours I had not met with any French or English translation, and which were, therefore, from my unacquaintance with the German language, unknown to me, I should in the interval look hastily over a very useful compilation which had but recently come into my hands, viz. Müller's Physiology, translated by Baly; not doubting but some notice would be taken of these recent researches, if they had really led to important results. I at the same time dictated the substance of my observations to my assistant, Mr. Kelburne King. Circumstances having occurred to prevent my examining Müller's work, the following observations were explained in detail to the

class, with a request that, until I had an opportunity of making the examination I had spoken of, I distinctly disclaimed all title to novelty :—

The whole of the structures to be examined were placed, when I first saw them, under clear spirits, and several sections having been made already through and through all the textures, quite into the cavity of the uterus, the examination was begun upon the margin of one of these sections.

On carefully pushing away the placentary mass from the uterus, several textures came into view : to take these in the order they were first looked at I shall commence with the surface of the placenta; I mean, of course, that surface which adheres *mediately* to the uterus. In the structure of the placenta adjoining this surface I could observe nothing more than what I had uniformly previously noticed, viz. minute vessels dividing and subdividing until they were just perceptible under the single lens I used. That these were arteries and veins there could be no doubt, since any separate bundle might be traced backwards to the larger vessels from which they came. In respect to any placental cells or cavities, or large placental sinuses, or decidual spaces, or placental spaces, I may as well say at once that no such structures were ever seen by me, and that I question, as I always did, the existence of such cavities or spaces.

Having traced certain minute branches of these placental vessels to that surface of the membrane interposed between the placenta and uterus (usually called decidua, but obscure in its real nature), the union of this membrane to the surface of the placenta was found to be comparatively firm, whilst its uterine surface adhered so laxly to the uterus, that it might be pushed from it to a considerable distance without destroying the anatomy of the intermediate textures or organs, owing to their natural elasticity. Being fully convinced, as I had been for many years, that to unravel the anatomy of these textures was to discover probably the whole secret of the mode of connection between the human fœtus and its parent, I dissected and observed these intermediate textures with the greatest care. To state in some sort of order what occurred at this point of the inquiry, I shall com-

mence by observing that the minute vessels I had seen in the substance of the placenta passed almost directly through the interposed membrane or decidua in numerous bundles, being bound at the same time to the edges of the apertures, through which they passed by a delicate but firm membrane derived from that surface of the decidua which faces the placenta itself. Having passed through it, some of these vessels were observed still to contain a dark-coloured fluid, which I naturally thought must be blood. So soon as these bundles of vessels had passed fairly through the decidua, they proceeded towards the inner surface of the uterus, enclosed, as it appeared to me, in funnel-shaped tubes, formed of a membrane connected as well with the inner surface of the uterus as with the uterine surface of the decidua. This membrane resembled a serous membrane, but is probably merely a cellular tissue condensed; extremely delicate, semi-transparent, and not unlike the arachnoid. Many other funnel-shaped portions or tubes had already been torn, so as to expose the placental tufts of vessels, and I tore through one or two of these tubes so as to be sure that they partially enclosed the tufts. It now became evident that the placental tufts did not terminate in these funnel-shaped tubes, but proceeding onwards adhered apparently by some means or other to the surface of the uterus itself: it was moreover now evident, that, to ascertain the mode of adhesion of the tufts to the uterus, was the desideratum. Tracing therefore, with every possible care, a bundle or tuft of vessels quite up to the surface of the uterus, it was found suddenly to disappear, plunging into an orifice leading directly into one of the venous sinuses of the uterus. In this sinus or cavity the placental tufts floated, extending a considerable way into the sinus, and having distinct terminations, that is, not uniting or anastomosing, so far as could be observed, with any other system of vessels. I now reversed the dissection: a uterine sinus was laid open more on that aspect which faced the substance of the uterus: it now seemed to me that the orifices by which the placental tufts had penetrated into the uterine sinuses were in no sense either the commencement or termina-

tion of the uterine veins, but merely lateral openings in the walls of the sinus; and that the peculiar pen-shaped orifices, described by many anatomists as seen on that surface of the impregnated uterus from which the placenta had been detached, and which had been declared to be the commencement of the uterine veins, shut up by the decidua so long as it is present, were appearances occasioned merely by an incautious dissection—a tearing away, in fact, of the placental tufts of the membrane which connects the tufts to the orifices themselves, and of a portion of the delicate inner wall of the sinus itself.

I now observed that the placental tufts, on entering the sinuses by the orifices I have just described, received a covering from the inner membrane of the sinus, reflected upon the tuft precisely around the orifice. Neither the time nor light permitted my observing whether these tufts were altogether loose within the sinuses, or had adhering points connected with the wall of the sinus; and, in respect to one of the tufts, it did appear to me to anastomose with another tuft which had entered by a separate orifice. The tufts themselves, in so far as I could make out without the aid of the microscope, seemed composed of longitudinal striæ, as if the vessels lay longitudinally to each other, and terminated by rounded extremities.

I may now proceed with the remaining points I purposed considering in this brief note; viz. 1. Whether or not a re-examination of the whole structures, favoured by more leisure and better light, would confirm, modify, or extend, my original observations made in March 1839. 2. Briefly to compare these observations with Müller's abstract of Weber's discoveries and inquiries: to this it was moreover necessary to proceed without delay, in order that the scientific public might have it in their power to decide previous to the publication of Dr. Reid's memoir, in how far these observations of mine agreed, or were at variance, with the discoveries of Weber. 3. To submit a few observations as to the probable extent to which Mr. Hunter's views might be reconciled with these later dissections.

Having obtained, a few days ago, a portion of the same uterus and placenta

on which my original observations had been made, improved however in this respect, that since the time I first saw it some fine vermilion injection had been thrown into the placental (umbilical) vein, I re-examined with a common lens, and under direct sun-light, these structures, placed as usual under clear water or spirits: again tracing the placental tufts through the decidua to the surface of the uterus, they were seen to enter the orifices in the walls of the uterine sinuses, after being enclosed in the funnel-shaped membranous tubes already described; in short, the only additional fact I was able to make out was the presence of some extremely minute injected vessels in the substance of the uterus. These were quite new to me, and unexpected; for, on being traced to their origin, they were found to be placental vessels; and that they were continuous with the umbilical vein, and of the same nature as the vessels composing the placental tufts, was inferred from this, that they contained seemingly some of the red coloured injected material which, as I have already said, had been thrown only into the umbilical vein. Thus another enigma comes to be added to the physiology of these structures, which, so far from clearing up the doctrines deducible from existing facts, tends rather to embarrass the whole. Here, then, is a subject clearly open for future investigation.

I next examined the uterine vessels, and more especially the uterine arteries, respecting the mode of termination of which there existed so many contradictory and unwarranted assertions; unwarranted, I mean, by any direct or intuitive evidence. As it had been asserted by Mr. Hunter, and by many others (amongst whom I believe I am entitled to include Dr. Reid), that these arteries terminate by open mouths of about the size of half a crow-quill, in the uterine veins, whether these veins be considered as terminating precisely at the surface of the uterus, or extended outwards, as Mr. Hunter thought, through the intermediate textures to the surface of the placenta, I gave my utmost attention to the careful dissection of several of the curling arteries of the uterus, commencing at a point where they were of considerable size, and easily distinguishable without any lens, and tracing them onwards

towards the surface of the uterus, until they became so minute as to be invisible under a strong pocket lens, and therefore at least twenty times smaller than the branches alluded to by Mr. Hunter, without in a single instance being able to satisfy myself that a single branch of any calibre whatever did really terminate in a vein. In fact, they divided and subdivided until they entirely disappeared. Not content with these repeated dissections, I obtained, through the kindness of Dr. Marr (Lecturer on Midwifery in Queen's College, Edinburgh), the uterus of a person who had died a few days after delivery of puerperal fever. A fine size injection, coloured with vermilion, was thrown into one of the uterine arteries; the uterus was then laid open, and many of these vessels traced through the substance of the uterus to the rough inner surface, to which it was evident the placenta had adhered. A loose cellular adhering substance marked this spot, together with a few clots of blood imbedded in it. Long before reaching this substance the uterine arteries had divided and subdivided to a great extent; many minute branches passed from the surface of the uterus into the cellular and gelatinous-looking substance adhering to its inner surface, ramifying in it in long fine filaments, out of which, however, the injection had, generally speaking, not been effused. Had the placenta been present, with its decidual membrane, I think it not unlikely but that these vessels might have been traced into it. In the meantime I ought also to remark, that not a particle of the coloured injection had escaped into any of the uterine sinuses. After this I conceive I have a right still to conclude, notwithstanding any authority to the contrary, that the mode of termination of the uterine arteries is altogether unknown.

2d. At the time I originally made these observations, I withheld their publication on the grounds already stated at the commencement of this note, and fully explained to my class at the time, viz. that they seemed to me to have been anticipated in all essential points by Weber. In what respect they may be found to coincide with Dr. Reid's more elaborate researches into the same subject, I cannot pretend at present to say, having seen but a very brief abstract of the memoir (in

the Athenæum) read by him to the meeting of the British Association held during the present autumn in Glasgow. I have also been further informed by him, that the abstract is extremely imperfect. At present he considers his views to be quite distinct from those of Weber, whose original memoir he has had the advantage of consulting. This memoir I have never seen, and beg leave therefore to quote the passage contained in Müller's Physiology, Part i. p. 249, from which I drew the inference that my own researches coincided with those of the distinguished German:

"*Absorption by organic attraction.*— The question whether the blood in the capillary vessels, or these vessels themselves, exert on certain substances an attraction which differs in its nature from any accounted for by physical laws, is quite distinct from the one above discussed. There is only one part of the body in which this kind of attraction certainly exists, and that is the capillary system of the placenta. The existence of lymphatics in the placenta and umbilical cord being quite problematical, the transmission of nutritive fluids from the mother to the child must be effected by means of the capillary vessels of the placenta. There is no direct communication between the vessels of the mother and those of the fœtus; the sole mode by which the uterine arteries terminate is by becoming continuous with the radicle uterine veins; and, on the other hand, the fœtal arteries of the placenta have no other mode of termination than in the commencing fœtal veins of the same part. Weber has given a very interesting description of the mode in which the placenta and uterus are connected. The finest ramifications of the placental vessels are distributed in the tufted processes on the maternal surface of the placenta. The arteries ramify in the tufted villi, and terminate at the extremities of the villi by direct inosculation with the radicles of the placental veins. Bundles of these tufts of villi project into the cavities of the large veins, in which the maternal blood flows on the inner surface of the uterus. From this arrangement of the tufts, and from the delicacy of the coats of the uterine veins, the fœtal blood circulating through the capillaries of the placental tufts is freely exposed to the action of the venous blood of the mother, and probably attracts from it some of the matters dissolved in it."

Now that my attention has been particularly directed to the above quotation, I certainly do perceive contradictory parts and assertions, which can scarcely be supported by a very strict anatomy; these escaped me when I first perused it. Still I am not disposed to consider these seeming contradictions as really affecting the merit of Weber's discoveries.

3dly. It now only remains that I should endeavour to shew in how far Mr. Hunter had seen and understood these textures, as we see and understand them now; but to do this satisfactorily would require a considerable extent of comment, which I have not leisure at present to attempt. Mr. Hunter has stated distinctly, 1st, That the placental vessels terminate in a fine spongy mass (placental tufts, Weber); 2dly, That the uterine veins terminate or commence on the surface of this spongy mass; 3dly, That the uterine arteries, whatever other terminations they may have, do also open upon the surface of this fine spongy mass, and into the uterine sinuses. I do not mean to deny that there are several seeming, if not real, contradictions in many passages of Mr. Hunter's memoir; that he mistook for veins the funnel-shaped membranous processes enclosing the placentary tufts on their way to the uterine veins; and that he fancied he saw, although I cannot believe that he did, the actual termination of the curling arteries of the uterus, &c. With these obscurities and difficulties, which after all may be merely in terms, I have nothing to do; but it is my firm conviction that Mr. Hunter saw precisely what Weber and myself have seen, and that he wanted merely sufficient confidence in the theory of "absorption by imbibition," to have expressed himself in totally other terms than what he did.

Newington Place, Edinburgh,

IODIDE OF POTASH IN PARALYSIS.

To the Editor of the Medical Gazette.

Sir,

If you consider the following case worthy a place in the pages of your

valuable periodical, you are at liberty
to insert it.—I am, sir,

<div style="text-align:center">Your constant reader,
Isaac Watmough, C.M. M.D.</div>

Porklington, Yorkshire,
    Oct. 27, 1840.

Mrs. D., aged 55, of stout habit and
sallow complexion, immediately after
breakfast on the 3d February last be-
came speechless, and paralytic on right
side. When I arrived she had just
been seized with a convulsion, which
again recurred.   She was bled to
twenty-five ounces, and a smart purga-
tive administered, and leeches to the
head. Convulsive attacks continued,
with distortion of muscles of face and
right eye. In the evening convulsions
ceased, complete paralysis of right side
remaining.

Next morning (4th), she was again
threatened with a return of the con-
vulsion ; and although the pulse was
feeble and compressible, with great
paleness of countenance, I recollected
the excellent remark of that high au-
thority, Dr. Abercrombie, of Edin-
burgh, viz. " Weakness of the pulse
and paleness of the countenance we
have seen to be frequent symptoms of
the worst forms of sanguineous apo-
plexy :" I bled her to syncope, and
blistered the nape of neck, used cold
applications to the head, with sina-
pisms to the inferior extremities.

On the 5th, bowels well acted on, but
no improvement ; there is a great ten-
dency to coma. She was now bled to
eight ounces, which made her faint ;
she soon rallied to her former state.

6th.—Symptoms still continuing, the
iodide of potash was ordered in three-
grain doses three times a day, and in
four days there was a marked im-
provement. Three weeks after the use
of iodide having been regularly at-
tended to, she having taken daily from
nine to twelve grains per day, she can
hold a needle in the right hand, but is
not able to feel it. This treatment was
persevered in for three weeks longer,
when she was completely restored to
her usual state of health, every symp-
tom of paralysis having disappeared.
I saw her lately, when she informed
me that she was sometimes affected
with headache, which was always re-
moved by a little purgative medicine.

MR. WARBURTON'S BILL.

The letter signed " A Physician,"
which appears in the present number,
and some others previously inserted, as
well as certain observations which we
have heard fall in the medical world, in-
duce us to recur to this subject, which,
when we last wrote on it, we had in-
tended to leave without another word to
the fate which all parties, including
even its author, anticipate for it.

Let us first set ourselves right with
our correspondent, Dr. Crosse, who, in
his praise of the proposed system of
registry, imagines that he has us for
opponents. So far is this from being
the case, that he will find that in the
number for the 2d of October we said
that it " would undoubtedly be advanta-
geous to possess the register for
other purposes than that which is con-
templated in the bill, namely, the election
of the officers of the new faculty." To
this opinion we still adhere ; but is it
not absurd that such a registration
should be made " rather an expensive
affair ?"—that when lists are kept by
each licensing body, and may be or-
dered to be published by them in one
general volume, an extravagant sys-
tem of registrars and subregistrars
should be entered upon ? Why, the
expense of this registration, added to
that of working the rest of the bill,
is expected to be so considerable,
that if a tolerably high tax levied on
each practitioner be not sufficient to
defray it, a vote of Parliament is to sup-
ply the deficiency, till (for Parliament
will not stand many such annual votes,

witness the case of the London University) the tax can be increased.

The advantages of an authentic list of the whole medical profession, stating the residence, the qualifications, and the dates of the licenses of each of its members, would certainly be considerable, and worth a small sum levied once or even annually on each person registered in it. But we repeat that we should " be taxed to purchase chains for ourselves," if we had to contribute any thing, however small, to the maintenance of such a bill as Mr. Warburton's, though it did bring with it the single solitary benefit of a registration. Besides, the whole benefit may be obtained, as we have already said, by the publication of a general list of the members of the several Colleges and Halls. Such a list is now published or made up annually by each of them separately, and the expense of uniting them all in one, and of including therein the names of all who were in practice before 1815, if shared among all the several licensing bodies, would be scarcely perceptible to any. At all events, it could be defrayed by the addition of a few shillings to each diploma or license hereafter granted. A respectable publisher might thus, for a few shillings, undertake to supply every one in the country, who has any interest in the matter, with all the benefit promised by Mr. Warburton's bill.

As for the rest of the bill we believe it has not met with the unqualified approbation of a single member of the profession. There are a few who think it might do *some* good, but their faint praise condemns it more certainly than the loud abuse of its hottest opponents, who, singularly enough, are to be found in the ranks of those who were expected and had promised to defend it. It is not easy to count the number of pieces into which the most active advocates of medical reform have split. A large, and the most respectable section, including those whose notions of reform were limited to the destruction of the monopoly of the highest medical honours by the ancient Universities and the College of Physicians, and to the improvement of the general standard of medical education, went off to the London University. The members of this section are now, in the minds of their former co-mates, ranked with the vilest of monopolists, and will evidently be the objects of their direct vengeance, should the true reformers—that is, the party not yet possessing their desired places of influence—ever come into power.

This remaining party has, of course, suffered some loss by Mr. Warburton's secession. He will take, no doubt, a few of the profession with him — he would not be so foolish as to endeavour to force a measure on a body of which no one member was his friend—but, what is more important, he will take with him a little parliamentary interest, and totally break up the small party that the two other reformers who indorsed his bill were able to form in the House. Mr. Hawes also, who has signified his intention to try his hand at legislation, with the doctors for his subject of experiment, will probably effect a rupture among the remaining ranks, similar to Mr. Warburton's; and small indeed will be the remnant left either in the profession or in parliament to Mr. Wakley.

Can a more absurd picture, or one more insulting to our profession, be drawn, than that of three members of the House of Commons agreeing to bring in jointly a certain measure, and, before it has even passed its first stage, separating and forming three distinct parties,

as hostile to each other as to those they used to call their common enemies? Yet thus it is with medical reform: the medical profession bill, brought in by Mr. Warburton, Mr. Hawes, and Mr. Wakley, conjointly, has only served to make way for the three distinct and opposing bills of its several authors.

The utter and signal failure of the schemes which have been in process of development for so many years, cannot but have one most desirable effect,— that of showing that, though the older institutions may have their faults, (and we appeal to our readers whether we have ever concealed or palliated any that really existed and deserved the name of faults,) there is no good to be hoped from those whose only object is to overthrow them; hoping that they themselves may gain some distinction by the change. Unfortunately for the cause, the chief of those who have seats in parliament, and who clamour so loudly for *medical* reform, are known as general radicals, and it is only, as they say of Mr. Warburton, " accidentally, or, as it were, incidentally," that they direct their passion against medical institutions. Place them in any other possible or imaginable situation, and such is their thirst for change, that, though they were in an Utopia, they would still clamour for reform. Place the laws of creation in their hands, and they would pretend to find them defective and unequal; they would see whether all the planets might not be made to move in one orbit, as well as, they are sure, all doctors might work in one faculty.

From such mere reformers for the sake of change we repeat no good can ever be expected; if there were in their ranks any one man who would point to any institution in this country, and say that he would take that as a model for

others of the same kind, or one who would conscientiously confess himself contented with any thing as it is, on this side the channel, we might believe his opinion on the state and improvements of the profession to be worthy of attention; but as far as we know there is not one such; and we believe, were their wishes established, their love of change would not be satiated till their own institutions were consigned to destruction.

Of this we believe the small body of ultra reformers have at length contrived to convince the great body of the medical profession; and henceforward the desire of the latter will only be, that existing institutions may continue to carry on in themselves those gradual changes which the alteration of circumstances, and the slowly improving state of society generally, require. Of late years there has evidently been no disposition to slackness in effecting these improvements; on the contrary, it might be fairly questioned whether a desire for popularity has not, in more than one instance, put prudence to silence. So long as an honest medical press exists, there can be no fear but that this progressive improvement will continue; and that in each of the several branches of the profession, (which are so adapted to the condition of the public, that were their differences obliterated to-day they would be virtually if not nominally restored to-morrow,) the best possible security both of the public and of professional interests will be obtained. As we lately showed, the progress of the profession, under the government of the existing institutions, has been most remarkable; so that there is scarcely a member who does not, unless for his own misconduct, occupy a much higher rank in society than his predecessors of the

same diploma; and from the very nature of things it is certain that we must continue in, or rise above, this relative position, if only the existing institutions are ready to make the necessary improvements in their examinations, and in other parts of their management, as often as occasions arise.

To suggestions for the improvement of the remaining defects in the medical institutions we shall not cease to give our impartial and anxious attention, and we would point to the letter of our correspondent, inserted to-day, as a model for the tone and temper with which such suggestions may be best made. Some of the recommendations which it contains are most judicious, and amongst them are several which we have constantly advocated. His scheme of education is not materially different from that now adopted, and in which we believe there is no need of any general change, though some of its details might, as we have at different times shown, be advantageously altered. The propriety of preventing druggists from practising without licenses must be evident to every one who considers the important functions that that class now performs. Brewers and bakers are prohibited by heavy penalties from poisoning, by never so slow degrees, their customers; but druggists may give, and even recommend and prescribe, their poison without restraint. It is obviously incompatible at once with common safety and common fairness, that the druggist should be allowed to be a medical practitioner without a license.

We earnestly recommend to our readers that part of the letter which contains the suggestions respecting the demand to show his license that it is proposed to make on each practitioner, and the mode in which punishment should be inflicted on the unqualified. We shall probably take occasion to recur to this part of the subject; meantime we may observe, that the suggestions of our correspondent on these points seem to contain the elements of much that would be advantageous.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

THE reform of the medical profession in Great Britain and Ireland is a subject which has so long occupied the public mind, and regarding which there seems to exist so intense an anxiety in a large number of the profession, that foreigners may be led to form an exceedingly low estimate of the medical men of this country. But it must be admitted that in no quarter of the globe are physicians and surgeons better paid, and more truly and justly respected, than in England: and, on the other hand, if we turn to the British army and navy, and the establishments of India, and the other parts of our vast colonial empire, our medical officers of every description will bear a triumphant comparison with those of every other government in the world. Therefore, let us not believe that the medical profession under the British crown, are the degraded caste which we might be led to suppose, from all which has been said on the necessity of medical reform; nor let us think that a remedy for existing evils is to be obtained by throwing this mass of supposed incongruity and imperfection into the crucible, and fusing it into *one faculty.* I will, however, admit, that there is room for improvement in the medical profession of this country; nay, it appears to me that great amelioration may be effected, without considerably disturbing existing institutions, or destroying the several orders of the profession as it is now constituted.

I beg to offer, through the medium of your journal, a few suggestions, which may be considered as the heads of a bill for medical reform; and, which it is hoped, will remedy some serious defects in our present system, and in no way obstruct further improvements.

I. That the medical profession shall continue as at present, to consist of physicians, surgeons, apothecaries or general practitioners, and druggists.

II. That the present medical licensing bodies shall continue to exercise their functions, but that they shall be restrained from granting diplomas or licenses, except under the following provisions, in addition to such others as the several licensing bodies may deem proper:—

1. Requirements for the degree of M.D. and the title of physician:—A liberal preliminary education; five winter sessions of medical study in some University, or in a recognised school of medicine, including all the branches of medical instruction, both theoretical and practical, excepting operative surgery.

2. Requirements for the diploma and title of surgeon:—A liberal preliminary education; four winter sessions of medical study as above, but a greater portion of time devoted to anatomy and surgery, and perhaps the exclusion of botany from the required course.

3. Requirements for the diploma of apothecary or general practitioner:— A sufficiently good preliminary education; three winter sessions of medical study as above; the time being chiefly devoted to anatomy, chemistry, materia medica, surgery, midwifery, theory and practice of medicine, and hospital attendance.

4. Requirements for the license of druggist:—A competent knowledge of medical Latin, and attendance on recognised courses of chemistry, materia medica, pharmacy, and botany.

III. That no physician's diploma be granted without three separate examinations, nor any surgeon's without two. All the licensing bodies to publish annually, in one or more newspapers, a list of the individuals to whom they have granted diplomas, or licenses, and a certified statement of the number of candidates rejected within the year. The licensing bodies to have the power of replacing by such eminent medical men as they may choose, those of their examiners who may be incapacitated by age or infirmity. The examiners to be paid a fee for each examination, whether the candidate be approved or rejected.

IV. That from and after the passing of this act no medical corporation shall have the right to prosecute any medical practitioner; and that this power shall thereafter be vested in the civil magistrate.

V. That the chief magistrate of each county and city shall call upon the practitioners of medicine and surgery, within his bounds, to produce evidence that they possess diplomas or licenses from one or other of the legally authorised medical examining bodies, or that they were medical practitioners previous to the year 1815: and in default of such evidence, the civil magistrate shall prohibit the unlicensed individual from practice under the penalty of — for each offence.

VI. That the name and designation of each practitioner, who has satisfied the magistrate that he is duly qualified, shall be recorded in a book to be kept for the purpose, on payment of a moderate fee.

VII. That all persons offering themselves as medical practitioners shall, previous to commencing practice, exhibit to the chief magistrate of the county or city in which they wish to practise, their respective licenses, which, if satisfactory, shall be recorded in the medical register of the city or district, on payment of a moderate fee; but otherwise the individual shall be prohibited from practising, under a penalty. An appeal against the judgment of the chief magistrate may be made to a jury at the assizes, and their decision shall be final.

VIII. That after the passing of this act no person shall be entitled to open a druggist's shop without a druggist's license, or that of a medical practitioner, and in default of such license he shall be prohibited, under a penalty, from selling any medical substance.

IX. That persons duly authorised to act as physicians, surgeons, or apothecaries, shall be entitled to practise in any part of the British empire, and it shall be competent for physicians and surgeons to act as general practitioners. But should any physician, surgeon, or apothecary, be convicted before a legal tribunal of a disgraceful crime, he shall thereby be deprived of his license to practise in any department of the medical profession.

X. All the existing medical examining boards shall be empowered to

grant licenses to druggists; and the colleges of surgeons shall be entitled to grant licenses to dentists, the candidates producing evidence that they have attended one course of anatomy and physiology, and received practical instruction in the art of the dentist. None other but surgeons and licensed dentists shall be entitled to practise this branch, unless already engaged in it; the civil magistrate having the same power as in the case of medical practitioners.

XI. That medical degrees granted by foreign universities shall not confer any right to practise in Great Britain or Ireland, unless among the natives of that country where the diploma has been obtained.

XII. That all persons applying for letters patent on account of inventions in the composition of drugs, shall be required to specify distinctly the ingredients and the mode of compounding each medicine, and a record of the same shall be kept for public inspection. Should any concealment or fraud be practised, the person so offending shall incur a penalty of —, and forfeit his letters patent.

The same specification shall be required, under the same penalties, from all proprietors of patent medicines, after twelve months from the passing of this act.—I remain, Sir,

Your obedient servant,

A Physician.

October 16, 1840.

ON THE PROPOSED
TAX UPON THE PROFESSION.

To the Editor of the Medical Gazette.

Sir,

It was not my intention to have troubled you again thus early, had not the letter of Dr. Crosse, of Norwich, inserted in your number for October 16, demanded, in my opinion, immediate notice; but on this occasion I take not up my pen in anger. neither shall my ink be gall. I will merely request the Doctor to reflect awhile on the position of the medical world, and compare it with that of the other learned and liberal professions. If he will condescend thus far, I have little doubt but his opinion relative to the proposed registration and tax will be essentially changed. With regard to the registration I need say nothing more, having in my letter of last week entered so fully into the subject; but the tax, I must repeat, I

consider highly objectionable. Have we not already paid the sum demanded by the College on obtaining the diploma? and is not that diploma a license to practise? If that license is to be annulled, who will present himself for examination? and what will become of the Royal College of Surgeons? Dr. Crosse thinks we ought to be taxed because the lawyers are taxed; but the cases are by no means parallel. The law is a much more lucrative profession than medicine, and leads to higher honours. A young man entering the legal profession may look forward to becoming, on some future day, Lord High Chancellor, or the first Minister of the Crown; but what has a young medical aspirant to look forward to? Let him examine the Court Kalendar; he will not find either physician or surgeon amongst the peers of the realm. We must be content to fag on year after year; and after many years' fatiguing practice—fatiguing both to body and mind (more particularly if, like Dr. Crosse and myself, he be a provincial practitioner), what has he gained? Does he retire with an ample fortune? Are there high titles, and lucrative situations of honour and distinction, to which he may aspire? or does he die in distressed circumstances, leaving a widow and family destitute? When Dr. Crosse considers this, I think he will change his opinion, and agree with me, that, instead of being taxed, we ought rather to be rewarded.

Of all the liberal professions that of medicine is undoubtedly the lowest, in respect of honours and lucrative appointments. Why this should be, I know not; and it certainly redounds little to the credit of so powerful and highly civilized a nation as Great Britain that it should be so. The Church (I crave pardon of its members for placing it after the law; but Dr. Crosse having instanced the law, induced me there to commence)—the church, lamentably ill as many of its functionaries are provided for, is far preferable to physic. How many of its lower orders, little dreaming of it at the commencement of their career, have risen to be bishops. The army and navy have the greatest honours bestowed upon them in the power of the Sovereign to grant; and that they truly merit them none will deny; but how are their medical officers rewarded, without whose assistance thousands would have perished, who are now in the full enjoyment of life and health? Without a surgeon, what captain of a man-of-war would take his ship to sea? Without a surgeon, what colonel would lead his brave followers to the field of battle? Without a surgeon, would Captain Parry have ventured on the polar expedition? Where are all these surgeons now? Have they titles, and honours, and lucrative appoint-

ments? Do we see them fluttering round the throne of the Sovereign, and basking in the sunshine of royalty? No; they, with probably a very few exceptions, are left to their own resources: many of them, deprived even of their half-pay, are at this moment fagging in country practice, and barely obtaining a decent maintenance.

I hope when Dr. Crosse looks at the argument in the light I have now placed it, he will, instead of favouring the idea of a tax, use his best endeavours really to benefit the profession to which he belongs, by raising them to that position in society which they ought to occupy.—I am, sir,

Your obedient servant,
G. HARVEY.

Oct. 20, 1840.

CLINICAL LECTURES,

BY W. DAVIDSON, M.D.,

One of the Physicians to the Glasgow Royal Infirmary, and Lecturer on Materia Medica.

ANEURISM OF AORTA BURSTING INTO THE ŒSOPHAGUS.

DAVID HARRISON, æt. 39, weaver, admitted 29th of June, 1840, complains of pain, feeling of weight and constriction in epigastrium, which extend along sternum to top of chest. Some cough, accompanied with palpitation and dyspnœa on the slightest exertion; slight mucous expectoration.

Is affected with frequent vertigo and faintish fits, and in the act of deglutition has a feeling of constriction or obstruction at top of sternum. Extremities affected with pricking and numb sensations : he is occasionally troubled with headache, and his sleep is disturbed with dreams. Skin cool; tongue white; bowels slow; pulse 84, of moderate strength; chest sounds well on percussion, and slight bronchitic ronchi are heard on both sides; impulse of heart is somewhat increased, its action regular, and second sound is converted into a prolonged rasp, which is also heard along the course of the large vessels as far as shoulders, and very distinctly, but mixed with a souffle, at top of sternum. A very distinct sound, between the sawing and bellows murmur, is heard along the course of the abdominal aorta accompanying its action. A slight souffle is heard over brachial and femoral arteries. Has complained of the thoracic pain for three, but first observed the palpitation one month afterwards.

R Submur. Hydrarg. gr. xii. ; P. Opii. gr. iv. M. Fiant pilulæ xii. una capienda ter indies.

Feb. 3rd.—For two days has been very hoarse, and is troubled with a stridulous

cough, and difficulty in expectoration. Second sound of heart is accompanied by a very loud cooing murmur, which masks the rasp, and it is heard over the whole of anterior and part of the posterior surface of chest. Some pain on pressing larynx ; sputa thin and watery. Very loud sibilant ronchi are heard over the whole of chest. Pulse 100, full.

Venesect. ad. ʒxx. App. Emp. Vesicat. sterno et cervic. anter.

Feb. 4th.— Percussion of anterior and superior parts of chest very clear ; not so much so in submammary regions. The cooing murmur which accompanies second sound of heart does not extend much beyond the cardiac region, and there is also a slight rasp present to-day. Cough very stridulous ; expectoration very difficult, being still thin and glairy ; loud sonorous ronchi are heard over whole chest, not so loud and harsh posteriorly as anteriorly ; cooing murmur of heart, heard in both supra-scapular regions. Twenty ounces of blood were drawn from arm, and it was slightly buffed. Pulse 100, of good strength; bowels regular ; tongue clean, moist.

R Ol. Ricin. ʒi. ; Submur. Hydrarg. gr. iv. Misce bene. Cap. Mistur. statim.
Abstrah. ʒxii. Sang. nucha cucurb. cruent.

Feb. 5th. — Percussion of anterior parts of chest clear ; cooing murmur of heart in cardiac region much less distinct, being accompanied by a slight rasp, but is heard over nearly the whole anterior part of chest ; percussion of back pretty clear, except in right scapular region, where it is slightly dull. Cooing murmur still heard in supra-scapular regions, but it is much less distinct. Sonorous rales are still heard over whole of chest, but are not so coarse, particularly in its posterior regions. Voice still very stridulous ; expectoration not quite so watery ; pulse 90, of moderate strength ; tongue whitish, moist.

Feb. 6th.—Cooing murmur less, and rasp more distinctly heard ; voice less hoarse and stridulous ; complains of dull pain in chest, anteriorly, on coughing ; expectorates a thin mucous fluid ; pulse 86, moderate.

Abstrah. ʒx. Sang. pector. cuc. cruent et postea app. Emp. Vesicat. Cap. Ol. Ricin. ʒvi. Cont. Pilul.

Feb. 7th.—Eight ounces of blood drawn by cupping ; pulse 86, soft ; pain of chest relieved ; tongue whitish ; feels much easier ; frequent stools from oil.

Feb. 8th. – Mouth affected ; tongue tolerably clean and moist ; pulse 84, of moderate strength ; sonorous ronchi much diminished, and percussion of chest is pretty clear. Cooing murmur of heart is still

heard in cardiac region, and in anterior and superior regions of chest, but the rasp is much more distinct; voice improving; cough less; bowels regular.

Omit. Pilul. Cap. Ol. Ricin. ʒi. Hab. Vin. Ipecac. gtt. xx. 4ta. q.q. hora.

Feb. 10th.—This morning at four o'clock was seized with hæmoptysis, hæmatemesis, and feeling of weight in thorax, nearly producing suffocation. When seen by clerk the feeling of suffocation had in some degree subsided, having continued only a few minutes; but expectoration of blood lasted for about an hour, and the patient may have lost about eight ounces. Acetate of lead was prescribed. Patient recovered from this paroxyism, and remained nearly in the same state as reported on 8th of Feb. until 11 o'clock A.M. when the hæmorrhage returned with great violence, and he died in about two minutes.

Inspection. — *Chest:* The lungs were bulky, very light and crepitant throughout their whole extent. The mucous membrane of the bronchial tubes was reddened, and their cavities filled with blood, which was coagulated in a tubular form. Some loose coagula were found in trachea and large bronchi. The heart was considerably enlarged, from hypertrophy of left ventricle, and dilatation of cavities of right side. The valves of heart were all healthy. The arch of aorta was very much dilated, forming a kind of pouch. Immediately below the point where the innominata and subclavian arteries are given off, there was a circular opening, having smooth round edges, which could admit the finger, communicating with a sac, of a somewhat triangular shape, situated between aorta, œsophagus, and trachea, and about the size of a small orange. On posterior wall of this cavity there was an irregular ulcerated opening, about the same size as former, and leading into œsophagus, about six inches from stomach. The aorta throughout its whole extent was considerably dilated, and studded over with large atheromatous deposits, which gave the inner coat a feeling of roughness, in some situations. *Abdomen:* Stomach enormously distended, and when opened was found to contain a firm clot of blood, of about four pounds weight. Some loose coagula in duodenum; mucous coat of stomach, and commencement of large intestines, somewhat ecchymosed   Liver large, natural in colour, slightly granular in texture. Kidneys pale-coloured and granular.

REMARKS.—In this case there existed very considerable difficulty in forming a correct diagnosis. There were, on the one hand, the signs of hypertrophy of the heart, and valvular or other disease of the aorta; and, on the other, some of those which accom-

pany aneurism of this vessel. As belonging to the first, the impulse of heart was increased, and a very distinct rasp accompanied its second sound. As belonging to the second class of symptoms, a distinct rasp was heard in the large vessels as far as shoulder, and more distinctly, but mixed with a souffle, at top of sternum. A sound between the sawing and bellows murmur was also heard along the course of the abdominal aorta. To these may be added the general signs, in the constriction in the chest, and feeling of obstruction at top of sternum, and difficult deglutition. The other pectoral symptoms were common to both affections. When admitted he had slight bronchitic symptoms, but these increased to a great extent in the course of about three days, the inflammation extending to the larynx, and accompanied with high febrile excitement. The general and stethoscopic signs clearly indicated a very general and pretty intense bronchitis and laryngitis. The most remarkable symptom, attending the bronchitic affection, was the substitution of the cooing murmur in the heart for the former rasping bruit. This cooing sound constantly accompanied the second sound of the heart, and at first completely obscured the rasp. It was heard most distinctly in the cardiac region, but it was also heard very distinctly in every other region of the anterior chest, except at its inferior margins; being loudest in the region of the heart, and decreasing as the distance from this organ increased. Dr. Hope, in his valuable work on the Diseases of the Heart, states that "the musical bellows murmur is a perfect note like whistling or cooing. In the case of a patient who applied to me for 'a noise in the chest,' I heard it at the distance of two feet. In a case precisely similar, which occurred to Dr. Elliotson, there was a very large and long vegetation in the mitral valve. I suspect, however, that the sound may possibly reside in the bronchial tubes, being created by the pressure of the heart during its systole, for I have several times heard it in the superior parts of the chest during the impulse of the heart, and then only. If this be true, it would be suspended, or at least modified, by holding the breath, or by making a complete expiration." This theory of Dr. Hope is a very natural one, and we were at first disposed to adopt it as a satisfactory explanation of the cooing sound in the chest of our patient; for this murmur was not observed until the bronchitis became severe, and became less distinct as this affection began to decline; but on causing him to suspend his respiration, no suspension, or the least modification of the sound, was discoverable. An imaginative person might found an hypothesis upon the alteration of

sound which might be produced by the ulceration which was going on between the aneurismal sac and the œsophagus; but we apprehend that a more rational explanation of it may be drawn from the atheromatous state of the aorta; and this view is supported by other cases which have come within the sphere of our observation, although we are far from thinking that they alone can determine this obscure point. The following is a case in point :—

Alexander M'Cale was admitted into the Glasgow Infirmary, July 2nd, 1840, complaining of pain in the right hypochondrium, some cough, great dyspnœa, anasarca of feet and legs. Countenance sallow, pulse 80, full, slightly jerking, skin hot, tongue white and dry. Percussion of left anterior and inferior regions of chest duller than those of right, except in right submammary region; and the respiration was somewhat bronchial in these situations. A thrilling vibratory motion is observed in cardiac region, and impulse of heart is increased. Both sounds of heart, particularly the first, accompanied with a cooing murmur, which is heard very distinctly over whole of left side, less so over right and in both carotids. Percussion of back rather dull, except in right scapular region; respiration somewhat bronchial in inferior dorsal regions, a little indistinct in both scapular. Cooing murmur heard double in left scapular region. Urine scanty, and a trace of albumen discoverable by the application of heat and nitric acid. This patient died on the 7th of July, five days after his admission; and the following were the post-mortem appearances :—

Inferior lobes of both lungs were reddish, engorged with a sero sanguineous fluid, and very slightly crepitant; bronchial tubes contained a mucous fluid, and their inner membrane was somewhat reddened. Heart very much enlarged, its left ventricle being enormously hypertrophied and dilated; the right side of heart seemed also to be somewhat hypertrophied and dilated. Considerable atheromatous deposits over whole surface of thoracic and abdominal aorta, and some were cartilaginous at the commencement of this vessel, immediately above its semilunar valves. There was also slight dilatation of the arch of aorta. Right kidney exceedingly hypertrophied, and its tubuli very much obliterated. Left kidney atrophied so much, that the cortical part only remained, and it contained several cysts. Liver very hard.

In this last case the cooing sound was equally distinct and remarkable as in the former one; and it underwent no suspension or modification by the patient holding his breath; and though the bronchial tubes were found slightly reddened after death, there was no peculiar symptom of bronchitis

present which could not be accounted for by the pneumonic engorgement of the lungs. The atheromatous and cartilaginous state of the aorta must therefore be considered the most probable origin of the abnormal sound in this case.

[To be continued.]

PURGATIVE EMULSIONS.

It is a common and a just complaint, that elegance of prescription is too little studied. The following emulsions from the French Codex will, therefore, prove acceptable to many of our readers.

Take of the resin of jalap, twelve grains; white sugar, an ounce; orange-flower water, two drachms; common water, four ounces; and half the yolk of an egg.

Triturate the resin with a small quantity of the sugar, so as to reduce it to a very fine powder; add the yolk of egg gradually, and triturate for a long time, in order to divide the resin perfectly; then add the remainder of the sugar, and the water in small quantities.

There is a similar emulsion made with twelve grains of scammony, four ounces of cow's milk, half an ounce of sugar, and two drachms of cherry-laurel water.

The last preparation is made with two pounds of the fresh leaves of the Cerasus Lauro-cerasus to four pounds of water, which are to be distilled, until two pounds of the distilled water have been obtained. On account of the depressing effects of this remedy, we apprehend it would be better, in many cases, to substitute orange-flower water, as in the previous formula.

TREATMENT OF STRANGULATED HERNIA.

Dr. Warneke recommends the following means, when those usually employed for the reduction of strangulated herniæ have failed. The patient is to take the following :— Opium, two grains; powdered belladonna root, four grains; sugar, four scruples. To be divided into eight powders, of which one is to be taken every half or quarter of an hour. The hernia is to be covered with a warm poultice, containing powdered belladonna, and bandages are to be placed pretty firmly round the upper part of the patient's thighs, close to the abdomen, to retard the return of the venous blood from the lower extremities, and render bleeding unnecessary. The author declares that by these means all the symptoms of strangulation are speedily removed, the patient falls into a quiet sleep and a profuse sweat, after which the hernia will be found soft and easily reducible.—*Medicin.Zeitschrift*, 1839, No. 38.

FATAL INFLUENCE OF THE EXHALATION FROM CHERRY-LAUREL UPON LEECHES.

About 700 healthy leeches, collected one bright summer's noon-day, were placed in two large glasses half filled with water, and covered with linen, and set towards evening between a cherry-laurel and a common laurel tree, so that their leaves and branches closely surrounded and covered the tops of the glasses. Next morning all the leeches were dead, and without doubt in consequence of the exhalation from the cherry-laurel tree.—*Archiv der Pharmacie*, May 1839.

NEW VACCINE MATTER.

The Royal Jennerian Institution of London employs now the same lymph which has been in use since the year 1806, when the institution was founded. According to this authority, lymph recently obtained from the cow does not generate a vesicle in any way superior to that produced by the old lymph (*Report of the Royal Jennerian Institution*, 1836). The same result was obtained in Italy in 1829, when the alarm of epidemic small-pox induced the Piedmontese physicians to try a variety of new stocks of lymph. We are informed by Dr. Griva (*Epidemia Variolosa del Torino*, 1829), chief of the Vaccine Establishment at Turin, " that no perceptible difference was to be traced between the aspect and progress of the old and the new, the primitive, and the long humanised virus." In Germany, the plan of recurrence to the cow has been largely tried of late years. In Wirtemberg alone, between 1831 and 1836, forty varieties of primitive lymph were successfully employed. The notion of superior efficacy attaching to the new lymph was, however, not generally entertained (*Heim, Kritische Darstellung der Pockenseuchen*). On the other hand, we are bound to acknowledge that the Small-Pox Hospital of London changed their old stock of lymph for more recent matter in 1837, and that a marked improvement was perceived in the resulting vesicles. The local inflammation was more severe, the constitutional symptoms were more violent ; the virus was more energetic, the most minute incision took effect, and the lymph given out on the ninth and tenth day was still in an active state. The National Vaccine Establishment has also, on several occasions, varied their stock of lymph with advantage. In France, a new variety of vaccine lymph, obtained from the dairies of Passy, near Paris, and called *Passy* lymph, was brought into use in 1836, and is considered by many as superior to the old stock. In 1838, Mr. Estlin, of Bristol, opened a new source of lymph from a dairy in that neighbourhood. It has been found very energetic and is now employed in many parts of England in preference to the lymph of the National Vaccine Establishment.— *Dr. Gregory, in the Library of Practical Medicine*, vol. i. page 326.

OBSTETRICAL CLINIQUE IN ST. JOSEPH'S HOSPITAL.

By Dr. Mazarem.

In the second quarter of 1837, 56 women were delivered of 58 children, there being two cases of twins. Of the births, 27 were boys and 31 girls ; three of the former and one of the latter were born dead. The forceps were employed twice, and there was one delivery by the feet. In one case the forceps were employed on account of epileptic convulsions, during which the pains at last entirely ceased. One woman died of uterine hæmorrhage, and no cause could be discovered, excepting inactivity and deficiency of contraction in the uterus after delivery. She was found dead in bed, and swimming in her blood, at two in the morning, hardly 24 hours after delivery. She had only complained of a feeling of anxiety, the previous afternoon, on awaking out of sleep. On dissection, the uterus was found full of coagulated blood, and much dilated.

Cæsarean operation eight minutes after the death of the mother.—A servant maid, aged 27, who had a disease of the chest, was admitted in a moribund state, at half-past nine on the evening of the 19th of May, and died in a quarter of an hour. The Cæsarean operation was immediately performed, and a dead fœtus of five months, of the male sex, was extracted. Disease of the lungs of long standing was found in the mother ; there was much serous fluid in both cavities of the thorax, and both lungs appeared as if macerated ; the left one was quite tuberculous.—*Zeitschrift für die gesammte Medicin*, from the *Jornal da Sociedade das Sciencias Medicas de Lisboa.*

COLD AFFUSION IN FEVER.

My little girl was last month seized with a very dangerous fever, which lasted twenty-one days. Having read in Dr. Currie's book of the happy effects produced in many cases by the application of cold water in fevers, I asked Dr. Pitcairn, who attended her, whether it would not be advisable to try it. He said he thought it certainly would, that it might be of great service, and could do no harm, but that the prejudice against it in London was so strong, that he never ventured to recommend it. Cold water was accordingly applied to her, and I have no doubt that it saved her life ; the delirium ceased the moment after it had been applied,

and all the symptoms of her fever became milder. — *Sir Samuel Romilly's Diary*, A. D. 1807.

DEATH OF DR. RUST.

To the Editor of the Medical Gazette.

SIR,

I WAS this morning informed, at the Prussian Embassy, of the death of Dr. Rust, which took place a few weeks since at his estate in Silesia, to which he lately paid a visit, and where he met with an accident which proved fatal to him. The loss, within so short a space of time, of Baron de Graefe, whose death was announced by the MEDICAL GAZETTE in June last, and of Professor Rust, who both, so much distinguished by their great talents and high scientific attainments, had been for many years the two leading men in surgery at the University of Berlin, and it might be said in Germany, will be deeply felt and much regretted, not only by their pupils, but also by the profession and public at large.

Should you deem this communication interesting to your readers, the publication of this note is at your disposal.—I am, sir,

Your obedient servant,

A. FRANZ, M.D.

19, Golden Square,
Oct. 28, 1840.

OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

PERMIT me to intrude on your valuable columns for a few lines to say that my first operation for strabismus was performed on April 7th, 1840, in the presence and with the assistance of Dr. Hingeston and Mr. Wardrop, Jun., and that this operation is the next earliest *on record* to those of Professor Dieffenbach's; that the idea of the blunt hook for passing beneath the tendon of the muscle originated with Dr. Hingeston and myself at the said operation, in consequence of our experiencing great difficulties in performing it after the method of Professor Dieffenbach, as described in Dr. Forbes's British and Foreign Medical Review; that had I been aware it was the custom of the weekly medical periodicals to publish essays on the same subject from the same individual, I should have gladly availed myself of the opportunity to have laid before your readers my original communications on strabismus; and that I am your constant reader and very obedient servant,

P. BENNETT LUCAS.

22, Argyll street, Regent-st.
October 18th, 1840.

Tuesday . 27	43	53	29·22	29·16

Wind S.W. on the 21st; W. on the 22d and following day; N.W. on the 24th and two following days. On the 27th S.W. in the morning, and W. in the afternoon.

On the 21st clear; the 22d, evening clear, otherwise cloudy, with rain; the 23d, morning clear, afternoon and evening cloudy, with rain; the 24th, generally cloudy, raining frequently; the 25th clear; the 26th and morning of the 27th cloudy, with frequent showers of rain; afternoon and evening of the 27th clear.

Rain fallen, ·565 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE VII.

Causes of disease, continued. Laws by which the operation of cold upon the bodily health is regulated. Circumstances that favour its injurious effects, and respect, first, the body itself; secondly, the manner in which the cold is applied. Modifying influence of certain states of the mind—of sleep—of habit. Means of protection. Influence of the different seasons. Impurity of the air. Hereditary tendencies to disease.

In the last lecture I commenced the consideration of some of the *causes* of disease.

We learned, by the evidence of authentic facts, that the human body is capable of bearing a very *high* degree of external temperature, for a short time, without detriment —and even without much inconvenience: and we learned—also by the testimony of facts—that the body is equally well calculated to endure, under favourable circumstances, a very *low* degree of atmospheric temperature—or, to speak in popular language, a very intense degree of *cold.*

It appears also that a high, but not extreme, atmospheric temperature, when long continued, has a stimulating effect upon the *organic* functions, and a depressing or sedative effect upon the *animal* functions of the body. Long-continued heat predisposes the body to be injuriously influenced by exposure to cold : the diseases apt to follow such exposure, under such circumstances, being derangement of the hepatic functions—vio-

lent disturbances of the stomach and bowels, with a copious discharge of vitiated and acrid bile—and acute inflammation of the liver itself. As more direct consequences of exposure to extreme heat—in other words, as examples of disorders of which extreme heat sometimes proves an *exciting* cause — I mentioned the *coup de soleil,* and the eruption called *the prickly heat.*

With respect to external cold, I pointed out to you its depressing effects upon the organic functions of the body—and, when it becomes very intense indeed, its directly sedative influence upon the animal functions also—producing a state resembling intoxication, overpowering drowsiness, and coma, especially when the cold has had an auxiliary in fatigue ; and, ultimately, death itself.

I hardly need say that the effect of external cold upon the body, within certain limits of intensity and duration, is totally different from all this. When it is not intense—or when, though intense, it is applied for a short time only—or when its refrigerating and sedative properties can be sufficiently counteracted by exercise and warm clothing—cold becomes a *tonic,* stimulating, refreshing, and invigorating both mind and body. Instead of benumbing, it heightens the sensibility ; instead of stupefying, it clears and sharpens the faculties, and inspires alacrity and cheerfulness of spirit ; and in this way, among others, cold becomes a very important curative agent.

Here also, therefore, the contrast obtains ; a high external temperature relaxes and depresses – a low one, under the circumstances just mentioned, braces and enlivens.

Nevertheless, exposure to cold is one of the most common causes of various complaints. Many or most of the internal inflammations acknowledge cold as their ordinary exciting cause. Acute rheumatism has, perhaps, no other origin. Apoplexy and palsy, and dropsy, are its frequent con-

sequences. "With the exception," says Dr. Bateman, in his *Observations on the Diseases of London*, "with the exception of a small number of diseases occasioned by unwholesome occupations, and by the contagions, the great mass of human malady in this metropolis is referable to the climate or state of the seasons, and to intemperance : but, of these two causes, the vicissitudes of the weather, especially its cold, are by far the most prolific sources of mischief."

It must, therefore, to every one who is engaged, or likely to be engaged, in the practice of physic, be a matter of first-rate importance, and of great interest, to ascertain the circumstances under which the application of cold is the most prejudicial, or has the greatest influence upon the body— as well as the means by which the bad effects of exposure to cold may often, in a great degree, be prevented.

There are some short but valuable hints upon this subject in Cullen's First Lines. The late Dr. Currie, of Liverpool, was, however, the first person who distinctly pointed out the laws that regulate the operation of cold as a cause of health and disease.

Of the circumstances which favour the morbific effects of cold, some relate to the condition of the body itself, some to the particular manner in which the cold is applied. The former are predisposing circumstances ; the latter accessary. We will glance at these in succession.

Predisposing circumstances. — It has long been a popular, as well as a professional axiom, that *sudden vicissitudes* of temperature are dangerous : that a *previous hot state of the body* augments the hurtful effect of the application of cold, either externally or internally. But the proposition thus broadly stated is not universally true. It is well known that the inhabitants of Russia are in the habit, while reeking from their vapour baths, of rolling immediately in the snow, or plunging into cold water, without suffering from the change. Sir Charles Blagden, describing some of the experiments which I mentioned in the last lecture, says, "During the whole day we passed out of the heated room (of which the temperature ranged from 240° to 260°) after every experiment, immediately into the cold air without any precaution. After exposing our naked bodies to the heat, and sweating most violently, we instantly went into a cold room, and staid there even some minutes before we began to dress, yet no one received the least injury." And Capt. Scoresby, speaking of the arctic regions, tells us that he has often gone from the breakfast-room of the vessel, where the temperature was 50° or 60°, to the mast head, where it was only 10°, without any additional clothing,

except a cap—"yet," says he, "I never received any injury, and seldom much inconvenience from the uncommon transition."

It is plain, therefore, that the proposition which assigns danger to sudden vicissitudes of temperature requires limitation. The effects of a sudden descent from one point to another in the scale of atmospheric temperature varies according to the state of the body at the time. Without going into any physiological discussion respecting the source of animal heat, I may just remind you of the faculty of evolving heat possessed by man and the warm-blooded animals ; by which faculty very nearly the same degree of inward temperature is steadily maintained under very different degrees of outward temperature. If the external temperature be lower than that of the body, the caloric thereby carried off is speedily replaced, in a healthy adult, by this evolution of heat from within, aided by clothing, or exercise. When the external temperature approaches the standard heat of the body, sweat soon breaks forth, and the superfluous heat is removed by evaporation : for so constant is the internal evolution of caloric, that an atmosphere which does not as constantly abstract any of it is excessively incommoding : an external temperature of 98°, which is about the average heat of the blood in man, is, as you know, extremely oppressive. The terms hot, warm, cool, cold, as applied to the surrounding air, are regulated by the sensations that it produces upon the average of persons. If the heat be carried off as fast as it is generated, and no faster, no particular sensation is felt, and the bodily powers are neither stimulated nor exhausted. This equilibrium is maintained, (supposing that no extraordinary exertions are made) when the thermometer stands at 62°, or thereabouts. We call that point in the scale *temperate.* All degrees above that point, up to 70, are reckoned *warm ;* all above 70, *hot.* Descending in the scale, we speak of the temperature denoted by any degree between the 60th and the 50th as being *cool ;* and every lower degree of temperature is *cold.* I am speaking of the average of healthy men : for remarkable diversities occur among individuals in respect to the names which they assign, under the guidance of their sensations, to particular degrees of the thermometric scale ; their sensations differing according to the power which their constitutions respectively possess of evolving heat. Now if this power of evolving heat, thus inherent in the system, be entire, and active, and persistent—if it have not been weakened by any of those circumstances which are known to have the effect of weakening it—no peril need attend even violent alternations of external temperature. Unusual heat of the body at the time when

the cold is applied, so far from implying danger, is really the condition of safety, provided the heat is steady and permanent. You may read, in Dr. Currie's book, numerous instances of the cold affusion being employed in the hot stage of fever, and particularly in cases of scarlet fever, not only with impunity, but with great benefit to the patient. The same holds true of the application of cold when the body has been heated by exercise — and, indeed, whatever may have been the cause of the increased heat—provided always that that cause remains steadily in action, that there is no local disease, and that the body is not fatigued and rapidly losing its heat. But if a person be already exhausted and weakened by exercise — if he be sweating and rapidly parting with his heat—and especially if the exercise is remitted, and he remains at rest immediately after the application of the cold—then it becomes highly perilous, and likely to produce internal mischief.

The more correct statement, therefore, respecting the application of cold is, that it is dangerous—not when the body is *hot*—but when the body is *cooling after having been heated.*

This principle applies alike, I say, whether the cold be applied externally or internally ; to the surface of the body, or to the mucous membrane of the stomach. Very many instances are recorded of death taking place immediately after a copious draught of cold water. I believe it will be found that in all these cases, the body, after having been much heated and enfeebled by severe exertion, was losing its preternatural heat from profuse perspiration, and, in general, from the cessation also of the exertion by which this heat was accumulated. Celsus was aware of the danger: " ex labore sudanti frigida potio perniciosissima est." The fatal influence of cold water thus applied was experienced, on a large scale, among the troops of Alexander the Great, upon their reaching the banks of the River Oxus, thirsty, fatigued, and perspiring from their toilsome march of forty-six miles across the scorching sands of the desert. According to Quintus Curtius, Alexander lost more of his soldiers on that occasion than in any one of his battles. " Sed qui intemperantius hauserant intercluso spiritu extincti sunt ; multoque major horum numerus fuit, quam ullo amiserat prœlio." Dr. Currie relates a striking example, which fell under his own observation, of sudden death thus produced. A young man had been playing a severe match at fives, and had violently heated himself. When it was over he sat down on the ground panting for breath, and covered with profuse perspiration. In this state he called to a servant to bring him a pitcher of cold water just drawn from a neighbouring pump. After holding it in his hand a little while, till he recovered his breath, he put it to his head, and drank a large quantity at once. He laid his head on his shoulder, and bent forwards ; his countenance became pale, his breath laborious, and in a few minutes he expired.

I may take the opportunity of telling you that the remedies to be administered, when life is in jeopardy from this cause, are warmth to the epigastrium ; and laudanum, in free doses.

If death does not speedily follow the external or internal application of cold to the body under the untoward circumstances I have described, inflammation of some internal part is very apt to arise.

By attending to the principles now laid down, you will be enabled to furnish those whom it may be your business to advise with many useful suggestions, and to caution them against some common mistakes : mistakes which have had their origin in the unqualified credit that has been given to the maxim, that sudden vicissitudes of external temperature, and exposure to cold while the body is hot, are dangerous ; whereas, these things are dangerous only under certain circumstances. Thus, you may tell the sportsman that wet feet, or a wet skin, need cause him no apprehension, so that he continues in active exercise ; and changes his clothes, and avoids all farther application of cold, as soon as the exercise is over. You may admonish the bather, that after walking in a hot day to the river's side, he had better *not* wait, to cool himself a little, before he plunges into the stream ; and in like manner you may venture to advise the young lady who has heated herself with dancing, not to linger in the entrance hall till the glow has somewhat subsided, but to make the best of her way to her carriage, and thence to her bed ; and you may tell your male friends, who happen to be similarly circumstanced, that the best thing they can do is to walk briskly home in their great coats. The main points to be remembered are, that the " heat which is preternaturally accumulated by exercise is held with little tenacity, is dissipated by profuse perspiration, and is speedily lost when to this perspiration is added a state of rest after fatigue ;" and that, in these circumstances, the application of cold is most apt to be prejudicial.

Among the circumstances which favour the morbific effects of cold, and relate to the condition of the body itself, is to be included—for reasons that will now be obvious to you—whatever has the effect of weakening the system, and so diminishing its capability of evolving heat. The most common of these debilitating circumstances are enumerated by Cullen — " fasting, evacuations, fatigue, a last night's debauch, excess in

venery, long watching, much study, rest immediately after great exercise, sleep, and preceding disease." All these, you will observe, tend to lessen the vigour of the circulation, and to depress the power of generating heat. Consistent with the same principle is the fact ascertained by M. Edwards, that the faculty of evolving heat is very feeble in old persons, and in the newly born ; it being in these classes that we find the greatest number of victims to the power of cold.

The bad effects of cold upon the system depend partly upon the intensity of the sensation it produces—but still more upon the duration of that sensation. We are seldom the worse for a momentary sensation of cold, however lively it may have been ; whereas even slight feelings of chilliness, if long protracted, are apt to terminate in some form of disease.

Accessary circumstances.—By the help of this principle we may explain most of the circumstances which, relating to the manner in which the cold is applied, have been found by experience to aggravate its hurtful influence.

Cold is more likely, *cæteris paribus*, to prove injurious when it is applied by a wind, or current of air. The sensation of cold is sustained by the continual accession of fresh particles of frigid air to the surface of the body. Some striking facts in illustration of the refrigerating and depressing effects of a stream of cold air were mentioned in the last lecture.

Again, the injurious operation of cold is augmented, when it is accompanied with moisture. Wetness is notoriously the worst way in which cold can be applied. The contact of wet or damp clothes with the skin both increases and prolongs the sensation of cold. For the same reason a cold foggy atmosphere is more prejudicial than a clear, and therefore drier one, of the same temperature. The heat of the body is abstracted more rapidly than it is generated from within, and if it be not replaced by exercise, or cordials, the balance of the circulation is deranged, and internal mischief often follows.

Counteracting circumstances.—The same principles serve to illustrate the effect of certain other circumstances, adverted to by Cullen, as being counteractive of the morbific tendency of exposure to cold : "passions engaging a close attention to one object"— "that state of the body in which sensibility is greatly diminished, as in maniacs,"—and "the power of habit." These circumstances are worthy of a moment's notice.

Abstraction of mind.—Impressions that are unheeded are unfelt and inoperative. As it is scarcely possible, when the attention is engrossed by bodily pain, to carry on any connected train of thought—so on the other hand the senses become impassive in proportion as the mind is fixed upon some absorbing subject of reflection, or enchained by some powerful emotion : impressions made upon the organs of sense are no longer taken notice of ; the corresponding sensations, if they are excited at all, are not remembered, and the effect of such impressions is as if they had never been ; they are not followed by the usual consequences. Persons gasping for breath in spasmodic asthma will remain for hours at an open window, with scarcely any clothing, during severe frost, and without suffering from the cold ; their attention is so anxiously and exclusively bestowed upon the distress in their breathing, that the coldness of the air is unnoticed and unperceived, and has no sensible effect. " For where the greater malady is fixed, the lesser is scarce felt." The morbific effect of cold upon the system is certainly modified by the degree of attention that is paid to the sensation it excites.

Insanity.—Upon the very same principle may be explained the impunity with which some maniacs undergo exposure to cold— even when suffering no fever which might regenerate the lost heat. "I have seen," says Dr. Currie, "a young woman, once of the greatest delicacy of frame, struck with madness, lie all night on a cold floor, with hardly the covering that decency requires, when the water was frozen on the table by her, and the milk that she was to feed on was a mass of ice."

Sleep is enumerated by Dr. Cullen among those conditions of the body which diminish its power of resisting cold. And certainly cold is very readily caught (as the phrase is), when its causes are present, during sleep. But while we sleep sensation is in a great measure suspended. This would seem, therefore, to furnish a contradiction to the principle that the effect of cold upon the bodily health depends upon the strength and the duration of the sensation excited by it. Dr. Alison—I speak from recollection of his observations heard many years ago— disposes of this difficulty by affirming that the sleeper who thus suffers does really feel, and is conscious of, the sensation of cold, and that it mingles with and probably suggests his dreams. Lord Brougham, in his *Discourse of Natural Theology*, gives a very lively picture of dreams so excited—drawn, as I should guess, from his own experience. Probably something of the same kind has occurred to most of us. " Every one knows (he says) the effect of a bottle of hot water, applied during sleep, to the soles of the feet : you instantly dream of walking over hot mould, or ashes, or a stream of lava, or having your feet burnt by coming too near the fire. But the effect of falling asleep in

a stream of cold air, as in an open carriage, varies this experiment in a very interesting, and indeed instructive manner : you will, instantly that the wind begins to blow, dream of being upon some exposed point, and anxious for shelter, but unable to reach it ; then you are on the deck of a ship, suffering from the gale—you run behind a sail for shelter, and the ·wind changes, so that it still blows upon you ; you are driven to the cabin, but the ladder is removed, or the door locked. Presently you are on shore in a house with all the windows open, and endeavour to shut them in vain ;—or, seeing a smith's forge, you are attracted by the fire, and suddenly a hundred bellows play upon it, and extinguish it in an instant, but fill the whole smithy with their blast, till you are as cold as on the road."

Certain it is, that though while sleeping we are not sensible of, or (what perhaps is the same thing) do not remember, ordinary impressions, we are nevertheless conscious of unusual sensations ; so that the facility with which we take cold during sleep is no real exception to the general law that the sensation produced by cold is concerned in its injurious effects.

Habit.—The last of the accessary circumstances mentioned by Cullen is "the power of habit." No one can doubt the effect of custom in enabling the body to resist the operation of cold, who has had opportunities of·observing how differently an inclement temperature is borne by persons whose employments oblige them to live much under the open sky, as shepherds, sailors, stage-coachmen—and by such as pursue in-door occupations—mechanics, tailors, shopmen, and the like. Probably the sensibility of the surface is blunted by habitual exposure. We may believe too that the purer air breathed by the out-door labourer, and his more active life, confer a more vigorous state of health, and endow him with an ampler faculty of evolving animal heat. The fact is unquestionable ; and we may sometimes turn our knowledge of it to good account, in gradually fortifying the system against the influence of cold that cannot be avoided. An ill-directed application of this principle has led, however, to grave errors, and cost many lives. You will now and then hear parents talk of *hardening* their children, by causing them to brave all sorts of weather, by teaching them to be indifferent about variations of temperature, to sit in winter-time without a fire in the room, and to despise great coats, flannel, and other additions to their usual dress. Fearing to render them effeminate by over care and cockering, they run into the opposite and more dangerous extreme.

This process is often attempted with children originally delicate, and to such it is doubly hazardous. During the early periods of life the inherent protective power of evolving heat is comparatively feeble ; and in this climate it requires to be carefully cherished.

The experiment of hardening should never be tried on any child or person that is ailing or unsound ; that shows any sign of present disease ; or any marked disposition to future, and especially to scrofulous, disease. Whenever it is tried it must be conducted in conformity with the principles already laid down. The subject of the experiment must be sufficiently clothed, and he must not fail to use such exercise during the exposure as may be requisite to excite and sustain the adequate generation of animal heat. An *abiding* sense even of chilliness must never be aimed at nor permitted.

The most direct and certain mode of fortifying the body against injury from accidental exposure to cold, is afforded by the use of the cold bath, and especially of the shower bath. When this is regularly taken in the morning, the surface of the body becomes enured to a degree of cold greater than it is likely to encounter during the remainder of the day. It is fortunate that we have an easy criterion of the propriety of continuing this expedient. When the sense of cold does not remain long, and is followed by a glow of warmth, the cold shower bath is sure to do good. If, however, after the bath, the person suffers headache, and continues long chilly, languid, and uncomfortable, it should at once be given up, as useless, and even hazardous.

By observing these simple rules, a healthy child may be made hardy also, without the risk, which their neglect would impose, of damage to his bodily fabric, and of abbreviating, by what was meant to prolong, his mortal span.

Influence of the seasons.—Closely connected with the effects of temperature upon the health is the influence of the different seasons of the year. A few remarks upon that influence, as it is witnessed in our own climate and country, may properly conclude our present subject.

It is open to the commonest observation that the general health of the community fluctuates with the changing seasons. Catarrhs, and coughs, and pectoral complaints of all kinds, are most apt to commence, or to grow worse, in the winter and spring months, while bowel complaints are more numerous and distressing in the summer and autumn. The mucous membranes of the air-passages sympathize with the skin under the agency of external cold—those of the stomach and intestines under that of continued atmospheric heat.

The thoracic disorders are more serious

and fatal than the abdominal. Various other maladies are likewise aggravated by cold, or by vicissitudes of temperature. Hence the mortality of the winter is always larger than that of the summer : unless indeed, this rule happens to be disturbed by the intervention of some widely-spread epidemic. I am not sure that the superior salubrity of the hotter over the colder portion of the year is generally acknowledged, even in this age of enlightenment.

It is the cold that, more than any other element of the weather, occasions the difference.

There are two small publications by the present Dr. Heberden, to which I would direct your attention, as being singularly instructive upon these points. One you will find in the eighty-sixth volume of the Philosophical Transactions : *Of the influence of cold upon the health of the inhabitants of London.* The other is a separate pamphlet : *Observations on the increase and decrease of different diseases.*

From a number of tables, framed chiefly upon the weekly bills of mortality, Dr. Heberden draws (in the last-named paper) the conclusion that the whole number of deaths is greatest in January, February, and March, and least in June, July, and August. This is contrary to the notions of the ancients —and perhaps of many of the moderns also. Celsus says, " Igitur saluberrimum ver est ; proxime deinde ab hoc, hiems ; periculosior æstas ; autumnus longe periculosissimus."

In his paper in the Philosophical Transactions, Dr. Heberden compares the number of deaths that took place in London in January 1795, which was an unusually severe month, with the number that occurred in January 1796, which was an uncommonly mild month. Of those two successive winters one was the coldest, and the other the warmest, of which any regular account had been kept in this country. In the month of January 1795, the thermometer, upon an average, stood at 23° in the morning, and at 29°.4 in the afternoon ; always, you will observe, below the freezing point. In the same month in 1796, it stood at 43°.5 in the morning, and at 50° in the afternoon ; always much above the freezing point. The average difference in the two months was more than 20°.

In the five weeks beginning with January 1st, 1795, there were 2823 deaths : in the five weeks beginning with January 1st, 1796, there were only 1471. The difference, 1352, is enormous. The mortality in the former year was nearly double of that in the latter.

One object which Dr. Heberden had in view in making this comparison was to disabuse his countrymen of the notion that cold frosty weather is more favourable to health than mild weather in winter ; a

notion which has been embodied in the proverb, that " a green Christmas makes a fat churchyard."

It is very instructive to remark in what classes of persons the injurious effects of the severe weather of winter is most felt. The increased mortality was found to be chiefly among the very young, and the very old : in other words, among those in whom the recuperative power of generating heat is the feeblest.

In January 1795 there were in London 717 deaths of persons above sixty years old, while in January 1796 there were only 153 such deaths; or scarcely more than one-fifth of the former number.

I have often been struck by the unusual length of the newspaper obituaries during periods of hard frost ; and by observing how many of the individuals whose deaths they record were far advanced in years. Dr. Heberden remarks that among persons older than sixty, the tide of mortality, as measured by the weekly bills, follows regularly the degree of coldness of the weather—so that any one accustomed to examine these lists may form a tolerably accurate judgment of the severity of any of our winter months, by noting the ratio of the mortality in persons above sixty.

The deaths from asthma (under which vague term all kinds of pectoral disorder attended with shortness of breath appear to have been included) were 249 in January 1795—only 29 in January 1796. In the former of these months there were 825 deaths attributed to consumption—in the latter 342.

All this accords with what I mentioned before of the effect of cold weather in producing or exasperating diseases of the respiratory organs.

One of the conclusions deduced by Dr. Heberden from his examination of the bills of mortality is, that " the number of deaths by palsies and apoplexies is in this country always greatest in winter." There are intelligible reasons for this. When the surface is chilled, and the blood driven out of the superficial vessels by the cold, it must accumulate in internal parts, and so press with increased force towards the head. And there is another reason for the frequency of these affections in the winter season : it is, as we have seen, the season of pectoral complaints, and of embarrassed respiration. Dyspnœa, and fits of coughing, greatly impede the return of the blood from the head through the veins : and cerebral congestion tends to the production of cerebral hæmorrhage, especially when the arteries of the brain are diseased ; and they often are so. Accordingly we find that in January 1795 there were fifty-two deaths from apoplexy and palsy—while in January 1796 the number was only thirty-one.

You may trace the influence of the seasons—not only in the prevalence of particular diseases in certain portions of the year—but also in the character of other disorders that are liable to occur in all periods of the year alike;—in the character, for example, of fevers. In the majority of cases of continued fever you will find that the pectoral symptoms are most troublesome in the spring, and the abdominal symptoms in the autumn. It is said also, but I do not know that this is so generally true, that affections of the head, in continued fever, are more frequent and severe in the winter, than at other periods of the year.

Impurity of the air.—*Mere impurity* of the air—by which I mean impurity that does not result from the admixture of any *specific* poison, such as the marsh poison, and the various contagions—is a powerful predisposing cause of disease. The prejudicial effect of impure air is seen, on a large scale, by comparing the inhabitants of great towns, in respect to health and longevity, with those who live in the country. In a valuable letter by Mr. Farr, appended to the *First Annual Report of the Registrar General*, a comparison is made of the mortality of about seven millions of persons, one half of whom dwell in towns, the other half in counties. "The concentration of the population in cities doubles the deaths from epidemic diseases, and disorders of the nervous system." In cities, as compared with counties, the deaths from consumption are increased 30 per cent, those from childbirth 71 per cent, those from typhus 221 per cent.

These differences we can explain only by attributing them to the weakening influence of impure air, and the want of sufficient exercise: for, as Dr. Alison has remarked, "it is hardly possible to observe separately the effect on the animal economy of deficiency of exercise, and deficiency of fresh air, these two causes being very generally applied together. But it is perfectly ascertained on an extensive scale, in regard to the inhabitants of large and crowded cities as compared with the rural population of the same climate, that their mortality is very much greater, especially in early life—and the probability of life very much less." There is one circumstance which shows that impure air is the more noxious agent of the two, namely, the very great mortality, in towns, of children under two years of age, even although they get as much exercise as their time of life would allow of any where.

The noxious and depressing influence of vitiated air is made strikingly manifest by the effect of a removal to a purer atmosphere. We are continually obliged to recommend "change of air" to our patients. We advise them to go out of London, that their recovery from acute disorders may be accelerated, and that they may regain the degree of general strength which is necessary to the cure of many chronic complaints; of all those especially that require the use of *tonic* medicines, among which class of remedies no one is so effectual, in constitutions that have been weakened by a town life, as removal to the clear and pure air of the country.

It is necessary, however, to remember that although impure air has most unquestionably a very hurtful effect upon the general health, there is no specific disease which can be distinctly traced to it as an *exciting* cause. It is as a predisposing influence that the impurity operates. For instance, it never *generates* (as I believe) continued fever, yet it will most certainly aggravate the symptoms, and favour the propagation, and augment the mortality, of that, and of other diseases, in a great degree. If there be any diseased condition that is strictly the product of impure air, it is scrofula. Scrofula (as I shall presently shew you) depends in part upon hereditary constitution; it partly arises also from exposure to cold and wet; but there is much reason for believing that impure air is a very powerful agent in calling scrofula into action, and in aggravating the strumous diathesis.

I have entered the more fully into the consideration of certain states of the atmosphere, its extremes and its variations of temperature, and its impurity, as causes of disease, because there is no part of the course in which I could more conveniently introduce them. Most of the other causes of disease, enumerated in my last lecture, will be discussed in connexion with the disorders to which they give birth: malaria, for example, when I speak of ague; contagions, when we come to the exanthemata and to continued fever; improper or insufficient diet, and intemperance generally, with indigestion, and the disorders of the alimentary canal; and so on. There is, however, one remarkable predisposing cause of disease, a few observations upon which may serve to fill up the little that remains of the present hour. I mean, that disposition to certain diseases which is apt to descend from parents to children: *hereditary tendencies* to disease.

Hereditary predisposition.—We must distinguish between *susceptibility* of disease, and a *tendency* to disease. In one sense all persons are born with a predisposition to most forms of disorder. No one is protected by nature against inflammation, when the causes of inflammation come into play. Poisons of various kinds, and specific contagions, which indeed are poisons, operate with tolerable uniformity upon *all men* alike.

But there are certain complaints which

we may separate in this respect from the others : which complaints some persons have a tendency to, and some have not. The tendency is sometimes strong and evident ; sometimes feeble and faintly marked ; sometimes it displays itself in the midst of circumstances the most favourable to health ; sometimes it requires for its development conditions the most adverse and trying. To mention some of these diseases : scrofula, which I shall soon describe more particularly, gout, mania, and (I believe I may add) spasmodic asthma.

Not only is a disposition to these complaints strikingly pronounced in some persons, but other persons appear wholly free from such a tendency, nay even devoid of the susceptibility of them. Gout, in those *capable* of it, may be acquired by habits, as it may be repressed and prevented by the opposite habits. The habits that, in certain persons, bring it on, are the intemperate use of the luxuries of the table, and an indolent or sedentary manner of life : but there are many people in whom no amount of rich living or idleness will generate gout. So there are some in whom no exposure to impure air, cold and wet, and no privations— in other words, no appliance of the circumstances calculated to bring the strumous diathesis into play, will ever produce any form of scrofula—will ever render them consumptive, for instance ; consumption being one of the most common and fatal shapes of scrofulous disease. There are many who never become afflicted with asthma, although surrounded by the most powerful exciting causes of that complaint.

Now with respect to these diseases, and perhaps a few others, it is matter of fact that they occur much more frequently in persons, some one or more of whose ancestors have suffered from them, than in other persons : the tendency is transmitted, is hereditary.

That the circumstances of the parents *do* influence the physical character of the children, no one can doubt : it is matter of daily observation ; and one of the best possible illustrations of the fact is to be found in what are called family-likenesses. We see children resembling their father or their mother ; or both parents at once, as mulattoes.

It has been suggested that the similarity in features and expression, and even in moral character, which cannot be denied to exist, may be ascribed to education and imitation. But allowing something to that cause, it cannot be all. It was, I remember, a common remark when I was at Cambridge, that the followers and admirers of a very good man, the late Mr. Simeon, appeared to come at last to resemble him. So man and wife are sometimes fancied to grow like each other. That is, the same

prevailing cast of thought and feeling—the idem sentire et idem velle—may give such an habitual expression and character to the countenance, as to superficial observers may constitute a likeness. But there are family-likenesses which will not admit of such an explanation as this : similarities in the shape or size, or disposition of peculiar features. Every one has heard of, or may remark in portraits, the hereditary thick lip of the Imperial House of Austria. Many persons now living have had the opportunity of tracing the lineaments of our own Royal Family through at least three generations. The sisters of one of our English Dukes are remarkably handsome young women, and bear, to this day, a striking resemblance to the portraits of their beautiful ancestress, the celebrated Nell Gwyn. And independently of the general cast of features, we trace these family likenesses in minute or unequivocal particulars—the colour of the hair and eyes, the shape of the limbs, the stature of the body, and so on : nay, in more decided peculiarities than these, in points of unusual formation. You have heard, probably, of the American calculating boy, Zerah Colburn. A great number of individuals of his family, descended from a common ancestor, had six fingers and six toes instead of five. The peculiarity was transmitted through four successive generations ; and probably, could his pedigree have been farther traced, through many more. I am myself acquainted with a gentleman who had the misfortune some years ago to have a bastard child laid to his charge. At first he had some misgivings on the subject, and suspected that he might have no real title to the credit (or I should rather say to the discredit) of the imputed paternity ; but all his scruples were satisfied when he found that the child had six fingers on each hand, for he had himself possessed two small supernumerary fingers, which had been amputated when he was an infant. Haller gives an account of a web-footed family, descended from a mother in whom that configuration existed.

Now there is one very curious circumstance observable in regard to these family-likenesses, namely, that they may fail to appear in the child, and yet appear in the grandchild : may skip over a generation or two ; may, after lying dormant, break out, as it were, in some collateral branch of the family tree.

This not only proves that certain physical peculiarities may be transmitted, but it discloses this curious property, that peculiarities *not possessed* by the parent may nevertheless be *transmitted* by him. And this evidently opens a wide field for the operation of hereditary tendencies. A person is not to consider himself as necessarily free from

a disposition to consumption or gout, because his parents have never shewn any symptoms of those disorders.

When one parent only bears the transmissible tendency, the disease appears to be most apt to break out in the children who most resemble that parent in their physical conformation and appearance : yet this is not a universal rule. I am acquainted with a gentleman who has lost several brothers or sisters by phthisis. The fatal disposition is known to exist on his mother's side, while his father's pedigree is believed to be quite free from it. All the children that have hitherto become consumptive have resembled the mother in bodily configuration and features, except this gentleman, who is like his father's family, but who, nevertheless, labours under unequivocal consumption.

It becomes a very interesting, and a very important question, whether *acquired* peculiarities can be transmitted. I have been told, by a gentleman attending the class, that he knew a man, who having been accidentally deprived of sight, afterwards propagated blind children. I believe, however, such an event is uncommon. Dr. Prichard is of opinion that all original or connate bodily peculiarities tend to become hereditary, while changes in the organic structure of the individual from external causes during life, end with him, and have no obvious influence on his progeny. Although this general law is probably true, I doubt whether it be yet sufficiently established by a reference to actual facts.

I need scarcely say a word respecting the importance to medical men, and indeed to all men, of a knowledge of these hereditary dispositions. Such knowledge ought to regulate, in some degree, the choice of persons wishing to marry. Where both parents have a decided tendency to any complaint, there will be a double probability of a diseased progeny. Lawful intermarriages between members of the same family are often highly objectionable on the same score. Any inherent defect or morbid propensity is aggravated by what cattle-dealers call " breeding in and in."

Again, if it be known that in any family an hereditary proclivity exists ; to gout and gravel, for instance, or to consumption ; this knowledge ought to warn every individual of that family sedulously to avoid the causes that foster and develop these diseases ; and medical men possessed of the requisite information may give most valuable advice and instruction on these points*.

* During the passage of this lecture through the press, the *Second Annual Report of the Registrar General* has been circulated, by the obliging attention of Mr. Lister, among the members of the profession. It contains much that illustrates and confirms several of the positions here

REPORT OF

PAROCHIAL LYING-IN CASES

(FOR EIGHTEEN MONTHS)

DURING 1839, AND TO THE END OF JUNE, 1840.

By James Reid, M.D.

Medical Superintendent of the Parochial Infirmary of St. Giles and St. George, Bloomsbury.

(For the Medical Gazette.)

580 cases—producing 589 children :—
305 male, of which 34 were still-born*.
284 female . . 31 . . ditto.
* The majority of these were of premature birth.

Age of the mothers.

Under	. . . 20	. .	24
Between	20 & 25	. .	158
,,	25 & 30	. .	169
,,	30 & 35	. .	155
,,	35 & 40	. .	50
,,	40 & 45	. .	21
,,	45 & 50	. .	3
			580

Unnatural presentations, complications, or accidents occurring after, or during, parturition.

Of the above 580 cases,

The breech presented in . . .	12
Feet	6
Face	2
Arm (these all occurred in twin cases)	3
Hand and foot	1
Funis with head	5
Funis with feet	1
Twins occurred in	9
Convulsions	2
Retained placenta (2 accompanied by hemorrhage)	10
Uterine phlebitis	1
Flooding before delivery . . .	8
Flooding after delivery	6
Lingering labour (those beyond 24 hours)	50
Premature births	41
Puerperal peritonitis	11

The *forceps* were employed in 5 cases ; *cephalotomy* in 3, and *version* in 2.

Mortality in the 580 cases, 5.

advanced. This immense yearly addition to the science of vital statistics is of the highest value. It cannot fail to throw light upon the sources, and to point towards the prevention, of many very fatal disorders. To ascertain the causes of any disease, and to display them before the public mind, are large steps towards their removal, so far as that may be practicable. The report itself, and Mr. Farr's able analysis of the registered facts, are replete with interesting and useful information.—T. W.

One female, who died the day after delivery, I have not included in the above number, as she had been discharged from more than one hospital as incurable, owing to disease of the heart. The excitement of parturition was sufficient, however, to hasten her death. On a post-mortem examination the heart was found to have enlarged to nearly double its size in health, and the lungs were diseased.

By a curious coincidence, another case of somewhat similar character was admitted the day after. I was requested to see her about twelve hours after the termination of her labour, as she was expected to die every moment. I found her apparently moribund, with a quick small pulse, cold clammy skin, her face and lips of a purple colour, and hardly able to articulate. The action of the heart was very irregular, and her respiration laborious. Without much expectation, I must confess, of its doing good, I ordered a small bleeding, to the extent of 8 ounces : it was, however, attended by very beneficial effects, and was again repeated during the night with advantage, as a violent cough had supervened. By the further application of blisters and leeching, and the internal use of mercury, antimony, and opium, she recovered sufficiently to allow of her discharge in three weeks' time.

Memoranda as to the preceding cases :—

In one case of arm presentation, both the hands were found in the vagina.— The mother, in *six* labours, had had *six* unnatural presentations.

In a case where the breech presented, the woman, in *eleven* labours, had had *ten* unnatural presentations.

A woman in three pregnancies had twice borne twins.

A woman had given birth to eleven boys in as many labours, and at length had a girl in her twelfth.

A case occurred of hydatid of the placenta. It was at first mistaken for a second bag of membranes.

The great majority of premature births took place in the seventh month.

One infant, born at the sixth month, lived twenty-six hours.

Another, at the same period, lived twenty-four hours.

In one case the woman, at full period, was delivered suddenly whilst standing in the street. Both child and placenta fell to the ground ; the former, though bruised, survived, and no injury occurred to the mother.

The largest child of the above numbers weighed 11 lbs. avoirdupois : it was still-born. The next in weight was under 10 lbs.

In adding the foregoing 580 cases to 600—the reports of which appeared in the MEDICAL GAZETTE of 1837 & 1838— and to 2,070 cases which I published, in 1836, in my MANUAL OF MIDWIFERY, the following will be the average result :—

Total number of cases, 3,250.

The breech & lower extremities presented in 79, or 1 in about 41, or 24·3 per 1000

Upper extremities	18,	180, or	5·5	,,
Face	15,	217, or	4·6	,,
Funis	16,	203, or	4·9	,,
Convulsions occurred in	8,	406, or	2·4	,,
Retroversio uteri	1,	3250, or	·3	,,
Rupture of uterus	1,	3250, or	·3	,,
Placenta prævia	3,	1083, or	1·	,,
Accidental flooding before delivery of placenta	23,	141, or	7·	,,
Ditto after	27,	120, or	8·3	,,
Placenta required manual extraction in	32,	101, or	9·8	,,
Forceps employed in	20.	162, or	6·1	,,
Crotchet	15,	217, or	4·6	,,
Version	20,	162, or	6·1	,,

Cephalotomy.

Jan. 22, 1839.—Maria Harris, æt. 27 (first pregnancy), came into the house on the 20th. Labour commenced on the morning of the 21st, and the liq. amnii escaped soon after. At noon the midwife found the head low down, and the os uteri fully dilated. Pains continued through the night, but without forwarding the descent of the child.

No movement of it has been felt by the mother since yesterday. I was sent for on the morning of the 22d, and was informed that the head had made no advance for the last twelve hours. I found that the rami of the pubes were approximated, and that there was likewise slight deformity at the brim. Vertex presenting. I tried to apply the forceps, but could not succeed with the second blade; and, from the fetid discharge, combined with the cessation of movement in the infant since the day before, there was little doubt as to its death, and as the head had already rested with strong pressure on one part of the vagina, I thought it expedient to use the perforator. The head did not collapse well, and there was great difficulty afterwards in effecting the passage of the shoulders, owing to the narrowness of the passage. This was evidenced, likewise, by strong marks of compression, which were observable on the thorax after birth. The patient did well.

Forceps case.

March 26.—Lydia Ives, æt. 40. First child. A coloured discharge had escaped for six days. On the third the liq. amnii escaped, but the os uteri was not at all dilated. Irregular pains. On the morning of the 25th, true pains commenced, but they did not become strong till 10 P.M. The presentation was natural, but a slight deformity at the brim of the pelvis was found to exist. On the 26th, at 2 A.M., there was no advance, and as the patient was becoming debilitated, I introduced the forceps, and extracted a female child, which had apparently died some hours previously.

Twins: Arm-presentation of one: Version.

August 1st.—Mary Hallen, æt. 27, residing in Griffith's-court. My attendance was requested by one of the parish midwives, to see this patient, at 5 A.M. Labour had commenced at 12 o'clock, and a male child had been born alive at 4, the vertex having presented. At 5 a second bag of membranes had ruptured, a great quantity of liq. amnii escaped, and a hand descended. On examination I found the right hand protruding from the vagina. I passed my hand up into the uterus, towards the abdomen of the mother, ascertaining that the umbilical cord had ceased to pulsate; beyond the head

a knee was reached, into the flexure of which my fore-finger was hooked, and the body was turned; the protruded hand not, however, receding much. The pains now expelled the second leg, and soon afterwards the left arm. As the child's face was turned towards the pubes, I turned the head round, and by placing a finger in its mouth, and pressing it towards the breast, it soon escaped.

Forceps.

14th.—Mary Ryan, æt. 30, second child, came into the house in labour at 12 at night. By 7 in the morning the head had descended low, but no progress had been made since that time till 12 (when I was requested to see her), although the pains had been frequent, and of a strong character. Her first child, she says, was extracted dead by instruments. As there was slight deformity of the brim of the pelvis, I at once employed the forceps, and a female child was extracted alive. The head was much elongated.

Cephalotomy.

Nov. 3rd.—Catherine Maloney, æt. 21, came into the house on the morning of the 1st, in labour. Slight pains continued during the day. The os uteri was partly dilated, but the infant could not be felt through it, and the membranes were not much distended by the pains. On the 2d, the os uteri was more dilated, but the membranes were now distended by the pains, which had acquired strength, although much advance did not take place in the progress of the labour. The fœtal head could now be felt above the brim of the pelvis. At 8 P.M. the membranes ruptured, and the head slowly descended till 6 A.M on the 3d. From this period, although the pains were regular and severe, no advance was perceptible. I was now sent for, and on my arrival found the os uteri fully dilated, and the head low down. Slight deformity of the brim existed, and combined with it the left ramus of the pubes projected inwards. After passing the catheter I endeavoured to use the forceps, but found their introduction impossible. There was an offensive discharge from the vagina, and the patient had not felt any movement of the child since the morning before. After waiting for four hours, I deemed it prudent not to hazard the risk of

further long-continued pressure on the vagina, and had recourse to the perforator. The head readily collapsed, and the child was extracted by the pincers and crotchet. The patient had no bad symptoms afterwards.

Funis presentation. Cephalotomy, and perforation of Chest and Abdomen.

Dec. 28th.—Mary Reeve, æt. 28. Labour commenced on the 26th, at 6 P.M. The membranes, it appears, had ruptured during the night, and a large quantity of liq. amnii escaped, but the midwife who attended could discover no presentation. On the morning of the 27th, the midwife returned, and found the umbilical cord in the vagina, but could not feel the child. Strong pains continued through the day; the head advanced slowly till the evening, but not perceptibly after this.

28th.—I was requested to see the patient at 4 A.M., and found the cord protruding, without any pulsation in it. The head was still above the brim of the pelvis, and owing to deformity in the antero-posterior diameter of the latter had not made any advance for the last six hours. Secale cornutum had been administered, although the bladder had not been evacuated for many hours. The patient informed me that her first child had been extracted alive by the forceps, but was small, and did not long survive. The second child, which was larger, was still-born. After introducing the catheter with much difficulty, I applied the perforator, and by the use of the pincers the head steadily descended; but although strong pains continued, the body did not follow. After waiting for half an hour, I inserted the crotchet into the left side of the thorax, and brought it sufficiently down to enable me to extricate the left arm. The pains being still insufficient for the completion of the birth, I used the same means with the right side. The abdomen, which now proved an obstacle, was found to be distended with air, and I punctured it with the scissars. The infant was then extracted: it was of large size, weighing, I should think, 9 lbs. The placenta came away soon after.—This patient, owing to the long period which had been suffered to elapse during labour without relieving the bladder, was afterwards the subject of vesico-vaginal fissure from sloughing. By the use of mechanical support, which I have before used in similar cases (and which I shall at another time describe), she now suffers but very slightly from this infirmity.

Forceps.

April 26.—Eliz. Bailey, 10, Newton Street. First child. I was called to this case, by a parish midwife, at 1 A.M. The patient had been in labour for twenty-seven hours. The vertex was low down, but in consequence of a very slight deformity of the brim of the pelvis, no advance had taken place for the last six hours. As the patient felt exhausted I applied the forceps, and a female child was extracted (living) with great ease.

Forceps.

June 9th.—Elizabeth Waylin, æt. 24, 14, King Street, Drury Lane. Sent for by Mrs. Backler, as the patient had been fifteen hours in labour. The head was low down, but though the pains were very strong and frequent, it had made no advance for some hours. The rami, both of pubes and ischia, were unnaturally approximated. This woman had borne four dead children (girls) previously. By using the forceps, a male child was soon born alive.

Puerperal Convulsions.

10th.—Ellen Healy, æt. 19. First child. This patient, residing in King Street, Drury Lane, suffered much from anasarcous swelling in the lower extremities: the labia being swollen to an immense extent from the same cause, I was requested to visit her. She had been married ten months, and thinks she is near her full time. She is a large stout-built girl, of leucophlegmatic temperament. I recommended that she should be removed into the Infirmary, and prescribed our common diuretic powders, which contain pulv. jalap. comp. with potass. nitr. These acted freely on the bowels, and she passed a large quantity of urine on the following day.

On the 11th she complained to the nurse of intense headache; but this was not made known to us till afterwards. Cold vinegar-and-water cloths merely had been applied to the head.

12th.—At 5 A.M. she was found to be rather delirious; the face was dark, and soon after a strong convulsive pa-

roxysm attacked her. 25 ounces of blood were taken from her arm by Mr. Wells, the resident surgeon, who immediately saw her. At 8 A.M. I saw her. The convulsions returned about every half hour, and were of a severe character. She struggled much even in the intervals, and was quite insensible : the tongue was slightly lacerated. On examination, per vaginam, the os uteri was felt high up, and undilated : the labia much reduced in size. I immediately abstracted 32 ounces of blood again from the arm, had the hair cut off, cold water poured on the head from a height, and cold lotion applied constantly to it afterwards.

12 A.M. No return of the convulsions: patient quiet, but insensible.

6 P.M. One fit this afternoon. Venæsect. ad. ℥xiij.

The os uteri had begun to dilate at 3 P.M., and on again examining it is found to be almost fully open. The patient is now sensible, but struggles much during the pains, and is very violent, so as to require restraint. Says she has a strong inclination to void urine, but is unable to do so. Catheter introduced, but no urine followed.

The pains continued till 11 P.M., but though the head had rested on the perinæum a long time, no convulsion returned until it escaped through the vulva, when a strong paroxysm occurred. The child was still-born, and of great size, weighing nearly 10 lbs. avoirdupois.

Hirudin. xij. tempor. Vesic. nuchæ.

13th.—Insensible ; pulse 100, and full ; respiration uneasy ; bowels freely relieved. The blister has not risen.

Rep. Vesic nuchæ. Vesic. ij. femoribus.

10 P.M. Skin hot ; pulse 90, and not so full ; still insensible. Blisters have risen well ; pupils strongly acted on by light ; cough, and difficult respiration.

Antimon. Potass. Tart. gr. 1-8th, omni bihor.

14th.—10 A.M. Has slept well; respiration free and regular ; is more sensible ; complains of nausea.

The antimony every four hours only.

On the 15th she had fully recovered her faculties, and went on very well till the 19th, when I found her dressed and anxious to return home, being quite well. I induced her to remain till the 21st, when she was discharged.

Twins. Second child born in an unusual position. Retained Placentæ.

June 15th.—My attendance was requested by a midwife residing in the parish, to see a woman, the mother of three children, who had been delivered of a boy on the 13th at 7 A.M., a few, but intensely strong, pains having sufficed to extrude the child alive. Another child was then discovered through the abdominal parietes, but there was no recurrence of pain, notwithstanding the administration of two or three doses of ergot, which was followed by no other effect than sickness. She remained thus totally without pain till midnight on the 14th, when pains suddenly returned, the right hand of the child coming down into the vagina. The midwife immediately sent off for me, but before my arrival the child was born, in a position which I have not before met with. The pains had been very few in number, but of the same intense nature as those which accompanied the expulsion of the first child. Under the influence of this strong expulsive action, the head was forcibly bent backwards on the spine (the face directed towards the sacrum of the mother), and *followed* the arm and shoulder. Not having met with a similar case, I questioned the midwife closely on the subject, and was by my inquiries satisfied that this was not a case of common spontaneous evolution, as the breech and feet were not expelled till after the other parts. The child, a female, of the average size of a twin, had apparently been dead for two days : its neck was more elongated than I have before observed, and its head very much compressed.

As the placentæ were not detached at the expiration of an hour after the birth of the last child, I became apprehensive that a state of atony of the uterus might supervene, accompanied by hemorrhage, and therefore passed my hand up through the pelvis, which was capacious. I found the uterus encysted at its upper part, and in this cavity were lodged both placentæ. That of the second child came away with facility, but the other was strongly adherent to the fundus uteri, and I had great difficulty in detaching it. The

uterus contracted well afterwards; the patient slept for some hours, and at the end of a week was out of bed, without having suffered from a single bad symptom.

Induction of premature labour; breech presentation. Forceps.

The following case has occurred since June (the period to which my general report extends); but as it presents some points of interest, I have here subjoined a statement of it:—Two labours, of the same woman, were formerly detailed in the MEDICAL GAZETTE for January, 1835, as from serious deformity of the pelvis: the perforator had been required in both. Her second labour was a breech presentation, and a strong band (the result of the former labour) stretching across the vagina, required to be divided by the bistoury before the body of the child could descend. The perforator was again required to release the head. In her third pregnancy, premature labour was induced at the seventh month, but the child, which passed with facility, was still-born. She has, since then, had four miscarriages at the fourth month.

Aug. 15th.—Catherine Davis, æt. 37. Eighth pregnancy. Catamenia last seen on Dec. 18: quickened April 5th. On Saturday, August 15, at 12 A.M., I pursued the usual means for inducing premature labour, as this period was, as nearly as I could calculate, about the eighth month of pregnancy. The os uteri was found to be so much dilated, that two fingers could be easily passed into it, and the bag of membranes was distinctly felt. No pains occurred on the Sunday, but they commenced, feebly, on Monday at 10 A.M. They increased in force and frequency during the afternoon, and at 5 P.M. became strong. I was sent for at 8 P.M. by the midwife in attendance, as it had proved to be a breech presentation, and the body was born, but the head could not be extracted. On my arrival I found that pulsation had ceased in the umbilical cord, and, on endeavouring to release the head by pressing the chin towards the chest, and applying two fingers of the right hand on the occiput, I was unable to move it. As the infant could not be beyond the eighth month, I applied the forceps, more as a guide to their use at a future time, if again necessary, than with any

hope of saving the child at present. The midwife holding the body of the infant, and drawing it gently towards the abdomen of the mother, the blades were applied without any difficulty, and the head removed.

Had the case, fortunately, been a vertex presentation, instead of the breech, the child, I think, might have been saved by the use of the forceps.

Puerperal Peritonitis.

It is a curious fact, that, with the exception of one or two isolated mild cases, puerperal fever has never made its appearance in the lying-in wards of our Infirmary, until the last winter. The first two or three cases were of a dubious character; the true nature of the disease was, perhaps, rather overlooked; and it was only after its breaking out in its intense form, that, to get rid of its fatal influence, we found ourselves obliged to employ all those precautions, which, in some larger establishments have so frequently been required. There was no prevalence of erysipelas or typhoid disease in the Infirmary, at the time, to account for its appearance (a fact which has been dwelt on as a coincidence in some hospitals). Indeed, we had a smaller number of typhus cases at the time than we had had for 18 months previously.

The following cases are to be classed, I think, in the FIRST form of the four adopted in Dr. Ferguson's excellent work on "Puerperal Fever." One or two reminded me, at the commencement, of the false peritonitis which he so well describes, and which I had opportunities of witnessing during my residence at the General Lying-in Hospital in the winter of 1824-25. In those the exhibition of Dover's powder, combined with the repeated application of hot linseed poultices to the abdomen, were sufficient to arrest the symptoms. Here, on the contrary, opiates seemed to afford but temporary relief in most of the cases.

CASE I.—Susan Radcliff, æt. 21, was delivered of her first child, on Sept. 30, in St. Giles's, having been attended by an old woman who occasionally officiated as a midwife, and who, according to the patient's account, handled her very roughly.

She was admitted into the house on the 6th of October; her infant was very sickly, refused the breast, and

died a few days afterwards greatly emaciated, its umbilicus having sloughed. The mother's milk decreased in the meantime, and she complained of uneasiness about the abdomen, attended occasionally with slight pain. The lochial discharge had ceased.

On the evening of the 15th Mr. Wells was called to her, as she complained of violent pain in the abdomen, increased by the slightest pressure, and accompanied by constant retching. Tongue slightly furred in the middle; pulse quick and small; face pallid; eyes sunken; extremities cold; the bowels had been relieved in the course of the day.

Hirud. xij. abdom.; hot fomentations. Morph. Acet. gr. ss. Mist. Febril.

16th.—Rather better; violence of pain has abated; pulse more natural (but still quick); extremities warm, bowels open; tongue furred, sickness continues. Abdomen tender, and rather tumefied.

Pulv. Hydr. c. Cret. gr. v. Pulv. Rhei, gr. v. M. ft. pulv. nocte maneque sum. Mist. Febr. Efferv. containing Ant. Tart.

17th.—Bowels much relaxed during the night; tenderness of abdomen increased; tongue furred; pulse more full; thirst and nausea continued.

27th.—Perspired somewhat during the night, for the first time; tenderness at hypogastrium returned.

Hirud. vj. Rep. Mist.; Rice diet. Morph. Acet. gr. ¼; Ung. Hyd. fort. abdom.

Nov. 4.—Has continued to improve, though slowly. The last two days troubled by diarrhœa, and passed some clots of blood: this was followed by small portions of putrid placenta. After this time she gradually recovered.

Case II. Oct. 21.—Caroline Collyer, æt. 18 (first child; duration of labour, twelve hours), complained, on the third day after parturition, of great tenderness in abdomen, which was preceded by shivering, and accompanied by febrile symptoms. She was bled to zxij., had eight leeches on the abdomen, followed by cataplasms.

Opii. gr. ss. Cal. gr. ij., every six hours.

She took afterwards a mixture containing Tr. Hyos. and Nitric Acid, and in the course of a few days was convalescent.

Case III. Nov. 1st.—Bridget Sheen, æt. 21: similar symptoms as the foregoing case, but not so violent. First child: labour 18 hours.

Hirud. viij. abdom.; Pil. Cal. c. Opio. Catapl.; M. Febrif. Ung. femor; M. Camphoræ c. Tinct. Hyosc.

Did well.

CASE OF

GRANULAR DEGENERATION OF THE KIDNEYS;

WITH REMARKS.

By Theophilus Thomson, M.D.

Physician to the Northern Dispensary, &c.

[*For the Medical Gazette.*]

Matilda S., aged 25, a pallid, sickly-looking subject, applied to me on the

17th of February in the present year, on account of swelling of the ankles and general debility. She had usually enjoyed an average share of health, but was always considered delicate, and her twin sister died at the age of ten. The patient had been delivered three or four months previously of a child, which she was still suckling. Her pulse was weak, but independently of simple debility, there were no prominent signs of disease. Griffiths's mixture was therefore prescribed, and she took it for a week with seeming advantage, the complexion improving, and the pulse becoming stronger. The state of the bowels was natural, and a pint and a half of urine of good appearance was passed daily. The swelling of the legs, however, being rather increased, she was directed to take half a drachm of bitartrate of potash, and a scruple of potassio tartrate of iron, twice a day. On the 28th of February, observing that notwithstanding an improvement in the general state of the patient the swelling of the ankles remained unaltered, I tested the urine with nitric acid, which threw down a curd-like precipitate, amounting in bulk to more than a fourth part of the liquid examined. She continued the medicine for a few days longer, without any apparent improvement. The patient now mentioned a circumstance, which she seemed previously to have forgotten, namely, that a month after her confinement, she had been caught in the rain while perspiring, and had been ill ever since. On the 3d of March, the urine being extremely albuminous, and the skin dry, I prescribed four grains of Dover's powder to be taken every night, twenty minims of antimonial wine in a draught of acetate of ammonia three times a day, and a small dose of castor oil occasionally.

On the 6th of March, the antimony appearing to irritate her stomach and impair her strength, was omitted, and she was directed to take acetate of ammonia in a mucilaginous mixture, to continue the Dover's powder every night, and castor oil every other morning.

Four days after the adoption of this plan the urine was found increased in quantity and less charged with albumen, and the skin was slightly moist. The patient continued to improve for about eight days, when in consequence

of imprudent exposure to the weather on a cold day, her state became less favourable, and the quantity of albumen in the urine was found to be as considerable as at the first examination. She was directed to confine herself strictly to bed, to take ipecacuanha instead of her draught of acetate of ammonia, and, on account of a costive state of bowels, to omit the dose of Dover's powder.

On the 24th of March there was little change in the condition of the patient, but the skin being obstinately dry, ten-minim doses of antimonial wine were substituted for the ipecacuanha ; the Dover's powder was again prescribed, and an occasional morning dose of castor oil.

No circumstance requiring notice occurred till the 31st of March, when there was some "lightness of head" and pain of loins. Six leeches were applied to the lumbar region, and four grains of James's powder substituted every night for the Dover's powder. The next day the skin was moist, and she seemed better, but on the 3d April I was informed that she had for two days suffered from headache. On visiting the patient, I found her materially worse, with some œdema of the face, and an expression of great depression. She raised her eyes languidly when addressed, and then closed them again as though only half awake ; and her replies were slow and incomplete. The respiration was oppressed, inspiration attended with a slight snoring, and expiration with a hissing noise, and there was occasional snatching of the right arm. The carotids throbbed violently ; the pulse was bounding, but not strong. During twenty-four hours the secretion of urine was almost suppressed. I directed six leeches to be applied to the temples, and a blister to the back of the neck, a dose of calomel and jalap to be given immediately, and five minims of tincture of cantharides every four hours. In the evening the patient became insensible, on which her friends, alarmed at her state, sent for a neighbouring practitioner, who opened a vein as she lay in bed, and removed about two pints of blood. I am told that during the bleeding her breath became more easy, and the snoring less decided, but she continued unconscious till the next morning. She then opened her eyes, nodded assent to

remarks made in her hearing, and after remaining sensible for about half an hour, suddenly expired. The blood drawn was cupped and buffed, and the quantity of serum so disproportionately great as to lead me to inquire whether any water had been added. The serum was analyzed by my friend and colleague Dr. Rees, and found to contain 1-24th of a grain of urea, and only 58 grains of albumen. Its specific gravity was 10·28.

On an inspection of the body twenty-eight hours after death, with the assistance of Mr. Hobbs, of Southampton Row, and Mr. Dalton, the following appearances were observed. Body thin, not œdematous, but extremely pallid; lips almost the colour of the skin; calvaria thick and dense; arachnoid natural; vessels of the membranes almost empty. Brain bloodless and firm; ventricles dry; left lobe of the cerebellum perhaps a little less firm than the right.

The left pleura contained ʒviij., the right ʒvj. of bloody serum. These membranes were not in the least degree reddened, but were in some parts covered with soft masses of lymph. The specific gravity of the effused serum was 10·25.

The heart was flaccid and distended. The left lung at its apex presented some cicatrices, apparently produced by the closure of some cavities now occupied with calcareous deposition. The intestines were very pale. The liver was healthy, and the gall-bladder full of dark bile. The kidneys were remarkably small* and seemed to be imperfectly developed, the papillæ being minute, and each ureter, instead of forming a pelvis, dividing into several branches as it entered the kidney. These organs were, however, evidently much shrunk from disease, and strongly adherent to their proper tunic, on separating which a distinctly mottled surface was very apparent. The substance of the kidneys was uniformly pale, chiefly in consequence of an abundant deposition of small granules, which were most numerous in the cortical part, but encroached so much on the tubular structure as almost to supersede it; furnishing a good example of gra-

* One of these kidneys is in the museum of King's College; the other in my own possesion.

nular degeneration of the kidneys in the last stage.

REMARKS.—1. The frequency with which albuminous urine has been observed to be associated with dropsical disorder, and the connection established by Dr. Bright between various alarming affections and this particular state of the kidneys, render it desirable to trace with care the phenomena attending any marked instances of the disorder. The case now detailed appears interesting more particularly on account of its uncomplicated character. So completely was all disorganization limited to the kidneys, and so little was their external appearance altered, that but for the researches of the distinguished physician above mentioned, the complaint of this patient would have been involved in obscurity, which even a post-mortem examination might have failed to remove.

2. It affords an example of death from coma entirely independent of arachnitis or cerebral effusion, but probably having relation to suppression of the renal secretion, and referrible either to the admixture of urea or of some other irregularity in the ingredients of the blood. It is true that the proportion of urea in the serum of this patient was considerably less than that which is occasionally found in those who recover from such complaints, but it is reasonable to suppose that, in susceptible subjects, the suddenness of its introduction materially increases the danger.

3. It serves in some degree to illustrate the favourable effects of the diaphoretic plan, to which the attention of the profession has been forcibly called by Dr. Osborne, of Dublin. This method of treatment is perhaps the most promising of those hitherto recommended, and acetate of ammonia and Dover's powder among the most appropriate of remedies of the class. In the early stage of the disorder, especially when the specific gravity of the urine is not much below the natural standard, diuretics may be useful, but in more confirmed and aggravated cases, with urine of low specific gravity, these remedies often tend to lessen the quantity of the secretion, and to increase the proportion of albumen. In some cases of considerable duration, I have observed great relief and even apparent cure

produced by spontaneous diarrhœa, but with the exceptions above noticed, and some others to which I may hereafter refer, I have rarely been able, in severe examples of the disease, to connect even partial recovery with the plan of treatment employed.

4. It illustrates the agency of the most common exciting cause of the disease, namely, exposure to cold and damp. The most frequent predisposing cause is probably a strumous constitution, but spirit-drinking appears to have considerable influence both in predisposing to the affection and in exciting it.

5. There remains the interesting question whether the disease be a cause or an effect of the attendant morbid condition of the blood. Several considerations favour the opinion that it is an effect. There are various phenomena consistent with the supposition that scarlatina, and other diseases tending, under some circumstances, to charge the blood with fibrine, may under other circumstances, especially in scrofulous subjects, occasion a surplus of albumen. In the early stage, this condition may sometimes be remedied, but when a morbid deposit of any extent occurs in the kidneys, an additional and permanent source of disorder is introduced, and new causes of general disturbance are brought into action. When no acute affection has preceded the occurrence of granular disease, it may be suspected that the fault lies primarily in the digestive organs, which fail to convert the food into healthy blood. To explain why a general cause of disorder operates on certain parts in preference to others may often be difficult, but in the circumstances under consideration it is reasonable to expect that the kidneys should first suffer, since they are the natural outlets for an excess of albumen. If the opinions now offered be supported by recorded phenomena, they authorize a conviction that our treatment of the complaint under review is likely to be satisfactory, not according to the importance which we attach exclusively to the state of the kidneys, but in proportion as we bear in mind the condition of the digestive organs, the nervous system, and the blood.

Keppel Street, October 1840.

To the Editor of the Medical Gazette.

SIR,

IN a paper "On the Incubated Egg," contributed by Mr. Towne to the 4th vol. of Guy's Hospital Reports, several facts are related apparently so directly opposed to the prevailing opinions regarding the decarbonization of the blood of the chick in ovo, that they at once attracted considerable attention, and moreover excited a very general feeling of necessity for some additional experimental inquiries into the subject, before admitting the validity of the conclusions that might be drawn from them. At the suggestion, and with the assistance of Dr. Sharpey, an endeavour was made to supply this obvious deficiency, and the results were stated by him in one of his lectures on embryology delivered in April last. Since that time the observations have been extended and confirmed; I have therefore taken the liberty to forward you a brief record of the same: the insertion of which in your journal, together with the accompanying remarks, will much oblige,

Sir,
Your obedient servant,
JOHN MARSHALL.

University College, Oct. 17, 1840.

The necessity for the occurrence of certain changes in the blood of animals during embryonic life, equivalent to those dependent on respiration in their adult condition, is admitted by all modern physiologists, who, relying upon the analogical arguments derived from the general unity of purpose, harmony of design, and simplicity of means, displayed in the same organic function throughout all its grades and varieties, have concluded that the blood during both periods of existence undergoes respiratory changes which, though differing in degree, are not only equivalent in effect, but perfectly identical in nature. According to this view, the elimination of carbon from the blood of the embryo, is (in part) effected by a mutual interchange between the gaseous elements of that fluid and those of the surrounding medium, whether it be air, water, or the maternal blood; the

oxygen consumed in this process, being invariably derived from a source extrinsic to the ovum, and in no case from the immediate decomposition of any previously existing chemical compound. Nor are these opinions founded upon theory alone; they receive confirmation from many incidentally recorded facts, as well as from the results of experiments intentionally performed, from which it appears that the due development of an embryo cannot occur without the presence of some oxygenated medium. The experiments alluded to are those of Jörg, Michelotti, and Spallanzani, on the ova of insects, and those of Reaumur, Viborg, Pfeil, and more particularly of Schwann, on the egg of the common fowl. Occasional facts have, however, been recorded, apparently tending to very opposite conclusions; namely, that the decarbonization of the blood of the embryo is independent of any external agent, that it is effected by means of decompositions and recompositions taking place within the ovum itself, and that the source of the oxygen is therefore altogether intrinsic. Of this character are the observations of Ermann and those of Mr. Towne on the egg of the fowl. The former of these have been successfully met and controverted by Schwann.[*] It is therefore the latter only that we propose to examine.

It would appear that the first doubts entertained by Mr. Towne as to the truth of the present views regarding the respiration of the embryo bird, arose from his having observed at the commencement and during the progress of incubation, a gradually increasing opacity and density in the lining membrane of the shell, which it was thought by him would offer a continually increasing resistance to the ingress and egress of gases. To those, however, who are familiar with the facts known relative to the diffusion of aeriform fluids, it will readily occur that every increased density of the membranes, from the deposition of earthy matter within, would be totally ineffectual as a means of preventing that diffusion. Moreover, it has been ascertained by Prout,[†] that, of the total loss sustained by an egg during twenty one days' incubation (amounting to 160 parts in 1000), 50 parts are lost during

the first week, 80 in the second, and 30 in the third. It is evident, therefore, that the shell and its membrane are quite as pervious (we do not assume them to be more so) during the second, as in the first week; and the relative diminution of loss in the third week cannot be regarded as proving an increased resistance to evaporation, until it has been shewn to be independent of all other circumstances. Again, Prevost and Dumas,[‡] state that the loss during the entire period of incubation is greater, in the proportion of 135 to 125, in impregnated than in unimpregnated eggs, although the lining membrane of the latter, according to Mr. Towne's own observation, undergoes no change.

Proceeding, however, upon this erroneous supposition, to seek for the proof on which the present theory of decarbonization is based, Mr. T. concludes it to consist in the fact, that the development of the chick in ovo has been prevented by rendering the egg-shell impervious to air by means of some varnish; but since the innocuous character of varnishes thus employed appeared at least very doubtful, he considered the experiments in question to be imperfect, and deemed it necessary to repeat them in such a manner as to " prevent entirely the admission of atmospheric air through the shell, and at the same time to avoid, as much as possible, the introduction of any foreign matter which might prove injurious to the embryo." With these objects in view he coated several eggs with four layers of paper saturated with liquid albumen, and also varnished them over several times with the latter substance; thus forming a covering, which, when dry, he " felt convinced was entirely impermeable." In all these eggs, when submitted to incubation, and also in another coated with five layers of the prepared paper and three coats of paint, the progress of development was perfectly natural: a result which appeared to him to be satisfactory and conclusive, as far as its hostility to the present theory of decarbonization is concerned.

The propriety of rejecting all experiments in which varnishes of a noxious character have been directly applied to the shell, cannot be denied, but it is incorrect to suppose that such experiments constitute the foundation of the

* De Necessitate Aeris Atmospherici ad Evolutionem pulli, &c. 1834.
† Philosophical Transactions, 1822.

* Annales des Sciences Méd. vol. iv,

received doctrine, which, far from depending on any isolated fact, or even on a single series of experiments, is at once indicated by *à priori* considerations, supported by analogy, and confirmed by the direct and unexceptionable observations of Schwann. Instead, therefore, of the apparently contradictory results, obtained by Mr. T., creating any doubts as to its truth, they rather give rise to a suspicion of some fallacy in the experiments themselves, and naturally suggest the question, were the coatings employed by him absolutely impervious to gases? To this, it is conceived, the following statements will afford a satisfactory reply :—

A circular opening, about an inch in diameter, having been made at the small extremity of several eggs, and their contents allowed to escape, one end of a piece of glass tube, a few inches in length, was accurately fitted into the orifice in each shell, and then secured in its connection by strips of tissue paper saturated with liquid albumen. In one of these compound tubes the line of junction between the shell and the tube was hermetically sealed with melted bees' wax. In two others the whole shell, and about an inch of the adjacent part of the tube, were covered with strips of paper softened in albumen, in the same manner and with the same precautions as were adopted by Mr. Towne. Seven thicknesses of paper were employed in one case and six in the other—one, and often two coatings of liquid albumen, intervening between the several layers ; and lastly, when all was dry, the junction of the shell and tube was effectually secured by means of three coats of paint. In this manner three diffusion tubes were constructed, the upper end of one being closed simply by an egg-shell and its dried lining membrane, those of the other two by that membrane, by the shell, and by the several layers of albuminized paper and albumen. On placing the open end of the first tube, perpendicularly into mercury, and then producing a difference in the level of that fluid within and without the tube, by alternately depressing and elevating the tube (about an inch and a half or less), the mercury on the inside rose or fell accordingly, the air being displaced through the porous shell and its lining membrane, and again re-entering in the way it had escaped. The same

experiments repeated with the second and third tubes, (closed with the coated shells) was attended with similar results, the rise and fall of the mercury being somewhat slower, but still sufficiently rapid to be perfectly visible to the eye of the observer. The three tubes were afterwards employed in hydrogen diffusion experiments, with the most complete success. On a close examination of the surface of the dried coating with a lens, it was observed to be traversed by a number of minute cracks, assuming every possible direction. Indeed it was found that thin layers of liquid albumen, even when dried at ordinary temperatures, invariably cracked in this manner—an event which the heat necessary for incubation would only render more certain of occurrence. It was remarked, moreover, that the application of a second layer of albumen only increased the number of fissures existing in one already dried, apparently in consequence of the freshly applied stratum itself undergoing a contraction whilst drying, subsequently to its union with that previously applied. The permeability of the covering of albuminized paper having been thus established and explained, the evolution of the chick in eggs so covered need no longer excite surprise. But since Mr. Towne also succeeded in carrying on development beyond the 12th day in an egg coated with five layers of the prepared paper and three of paint, the diffusion tube, No. 3. (already covered six times with paper) was painted over three times, and another tube was prepared and covered in the same manner, but so contrived that the lining membrane of the shell was kept constantly moist during diffusion experiments in which carbonic acid gas was employed. In neither of these tubes, even when the experiments were continued for four weeks, did the slightest mechanical permeation or diffusion occur. It by no means follows, however, that the single egg painted by Mr. T. was equally impervious to air; on the contrary it may be safely asserted that evolution could not have proceeded naturally for 12 days, had the access of air been effectually prevented. The observations of Schwann, indeed, afford evidence, as strong as negative results can do, that without oxygen normal development is arrested after the 15th hour; but since results of a negative

character become valuable only in proportion to their number and constancy, the following experiments were performed with a view of adding to the one, and of submitting the other to still further tests :—

Out of a number of newly-laid eggs obtained from the same poultry yard, some (taken indiscriminately) were covered twice with portions of bullock's intestine, fresh, well washed, and thoroughly cleansed from fat; this double covering was tightly applied over the egg, so as to leave no intervening air, and was carefully secured at each end. After becoming dry they were covered three or four times with strong glue-size (applied only lukewarm) containing a small quantity of sugar to prevent its cracking. They were again allowed to dry, and were then placed under olive oil, in an incubating machine, together with the remainder of the eggs obtained at the same time and from the same source, which were simply supported above the surface of the oil. Four eggs thus covered and placed under oil, with three in their natural condition, were employed in the first experiment, in which incubation was continued 108 hours; in another, six covered, and under oil, and six uncovered, were used, the period of incubation being 120 hours; and in a third experiment the same numbers were again employed, one of the covered and uncovered eggs being examined at the end of the 7th, 13th, 20th, 32d, and 48th hours.

In two out of the sixteen eggs thus incubated under oil, the membrane of the yolk adhered to that of the shell, and the blastoderma was accidentally ruptured in opening them ; but in the remaining fourteen its precise condition was carefully examined ; and it was ascertained, as in Schwann's experiments, that development had been limited to a mere extension of the germinal membrane, though to a greater degree perhaps than had been noticed by him, in some having obtained a diameter of an inch and a quarter. In none of the sixteen eggs, however, was there any trace of embryo or blood.

Against these experiments three objections may possibly be urged—one having reference to the use of the oil, another to the fertility of the eggs, and a third to the degree of care with which the artificial incubation was conducted. To the first of these objections it will be sufficient to reply, that, on removing the eggs from the pan of oil, the glue-size was always perfectly firm and entire; that the outer portion of intestine adhered intimately to the inner one, and this again most closely to the shell; that no greasy spots could be detected on the latter ; and lastly, that no diffusion occurred in a compound tube fitted up with an egg-shell covered in the same way. From all these facts it may be safely inferred that the oil could not have penetrated even to the shell.

In answer to the two latter objections it may be remarked that, out of eighty-four eggs, obtained from the same source, and artificially incubated by myself during the past summer, in three only were there no traces of evolution; that out of the fifteen placed in the machine along with those under oil, only one failed; and finally, that in fourteen out of the sixteen incubated under oil, the actual occurrence of development, though of an abnormal character, afforded abundant proof of their fertility, and at the same time gave a positive character to experiments which otherwise would have been merely negative.

It is almost superfluous to remark, in conclusion, that the preceding results entirely coincide with those obtained by Schwann, and harmonize with the generally received opinion regarding the extrinsic origin of the oxygen employed in the respiration of animals during their embryo life ; for the facts ascertained with regard to the ova of birds cannot be limited in their application to that particular class of animals, but must aid in extending our knowledge concerning the nature of the respiratory function in every kind of ovum.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A Practical Work on the Diseases of the Eye, and their Treatment medically, topically, and by operation. By FREDERICK TYRRELL, Senior Surgeon to the Royal London Ophthalmic Hospital, &c.

IT can scarcely be expected that we should undertake to give a digest of

the contents of two large volumes on
this subject, or even of all the novel-
ties and peculiarities which they con-
tain ; for although, after the publica-
tion of so many treatises as have ap-
peared of late years in this most fertile
of all surgical fields, it is certain that
no one writer could offer much that
had been previously unwritten, yet he
would be a bold reviewer, who, in a
case like this, would undertake to claim
and establish for any new author all
that he may seem to merit for origina-
lity either in the description or in the
treatment of ophthalmic diseases. It
would be difficult to do so in any case,
but in none more than in the present ;
for Mr. Tyrrell affords no clue by
which one could detect for how great a
portion of his knowledge in this branch
of science he is indebted to others.
His volumes present a feature singular
in this department of surgery—that of
an almost absolute absence of reference
to any others, except in the very rare
passing allusions which they contain
to the habitual practice of Mr. Saun-
ders, and a few others. And we believe
that in this there is no intentional con-
cealment of the assistance that the
author has received from reading, but
that he has, in fact, worked out,
by himself almost, the whole sub-
ject of ophthalmic surgery so far
(and this is to no small extent), as
he is acquainted with it. The uni-
versal and most prominent character of
the work is, that it is eminently prac-
tical; if the pages were counted we
believe that at least three-fourths would
be found to be directly connected with
the treatment of disease, and not
one-tenth which have not more or less
evidently that object distinctly in view.
In short, Mr. Tyrrell has here given, in
an orderly manner, all the convictions
with which he has been irresistibly,
and perhaps imperceptibly, impressed
during twenty-two years' service as as-
sistant and full surgeon to the Eye
Infirmary ; and although he may seem
to hold to some of his opinions and
modes of practice with more tena-
city than the observations of others
would warrant, yet on the whole there
is probably no work which the
practitioner could more safely take as
his guide in the treatment of oph-
thalmic diseases.

In other respects than this relating to
the details of treatment, Mr. Tyrrell's
work is inferior to some that have pre-
ceded it, both from English and from
German authors. Those of the German
school especially surpass it in accuracy
of anatomical details ; and one could not
have a better proof that the present work
is not indebted to any of them for the good
that it contains, than the imperfect-
ness and sometimes inaccuracy of its
anatomical details, which are such
as no one acquainted with German
ophthalmic literature. even by trans-
lations, could have fallen into When,
for example, it is said (vol. i. p. 210),
" We cannot, from simple anato-
mical examination of the cornea,
trace any organization, as neither arte-
ries, veins, nor absorbents, can be de-
tected," we perceive at once that the
writer never read that its arteries have
been injected (by Romer and others)
passing from the conjunctiva towards
the centre of the cornea, and on their
course bending into the substance of
the latter, and that even its nerves
have been distinctly and visibly de-
monstrated by Pappenheim, Schlemm,
Bochdalek, and others, and that their
arrangement forms part of received
anatomical science in every school in
Germany. We might point out similar
deficiencies, and occasional errors, in
the anatomical description of all the
other tissues of the eye ; and for these,
if anatomical accuracy be, as is gene-
rally held, the first step to surgical
certainty, a systematic writer can claim
no fair excuse, after he has had the
opportunity afforded him of reading
the more true descriptions in his own
language, in this and other contem-
porary journals, and in the various works
recently published on physiology.

But we rather fear that the step is
not short between the anatomy of the
eye and the cure of its diseases, and
that here, as in every other part of
medicine, it is a fortunate rarity when
physiology can suggest or encourage
successful practice. Mr. Tyrrell's prac-
tice is certainly an example of this
melancholy truth ; his anatomy we have
shewn is often defective, sometimes
incorrect, yet his treatment of the dis-
eases of the eye is, we know, and hun-
dreds of his pupils can confirm our
statement, as successful as that of any
ophthalmic surgeon in Europe, and
far more so than that of those who
could best improve his knowledge of
anatomy. It is in vain to deny that

the instances are numberless which prove (whatever introductory lectures may say) that anatomy and practical medicine at present go on in distant and not even parallel lines of progress ; and that if the one *must* be the foundation of the other, and can alone support it securely, the superstructure of scientific and successful practice will not be raised to an appreciable height for centuries to come, although during all the time before that consummation arrives disorders may be satisfactorily alleviated and cured by the rules of simple and well-matured experience.

Mr. Tyrrell's practice we have said is well known to be remarkably successful, and it is fortunate that the portion of it which is most peculiar to himself is capable of imitation by any discerning and cautious practitioner. The modifications of some of the operative proceedings which he has introduced, require, that their full value may be obtained, no inconsiderable share of the perfected dexterity of their inventor ; but these form only a small portion of that which will be found useful in his suggestions for treatment.

The most valuable part of his work is undoubtedly that which treats of the medical management of the various diseases, and especially those which are so prolonged and tedious, that, in the majority of cases, both patient and physician would give them up as hopeless. But mere long continuance of disease seems to give Mr. Tyrrell comparatively little uneasiness : if the disease were long in establishing itself, then must the surgeon be patient in his endeavours to uproot it, and months, or even years, must pass before the steady employment of means that are sure to benefit, if not to cure, must be desisted from. It probably adds to the confidence with which he adheres to the treatment of a case, however long it is in giving visible encouragement, and to the energy with which he is enabled to persuade the patient to keep steadily to his plan, that Mr. Tyrrell believes all that he does for the diseases of the eyes is founded on strictly determined rules of pathology. And, indeed, when the result is so good, we know not if it would be wise to question the truth of opinions upon "power" and "debility," and "insufficient arterial action," and so on,

lest the confidence in the treatment which they are supposed to suggest should be loosened. Still we cannot help suspecting that the author's theories, instead of suggesting his practice, are really all *ex post facto.*

The chief novelty in practice, which Mr. Tyrrell has more than his predecessors encouraged, is that of admitting a generous diet, and administering steadily a course of slightly tonic remedies, in nearly all cases of long standing, and obstinate inflammations of the different parts of the eye. Nearly all these he holds are the result of insufficient power in the system to remove the evils which have resulted from some disease, perhaps accidentally introduced ; in other words, of some general debility by which the body is rendered unable to cure, by its own efforts, a local disease. The sovereign remedy for these affections is bark and carbonate of soda, five grains of each three times a day, a mild but generous diet, and the most careful attention to the general health. These, and the administration of numerous, but small doses of mercury, in particular cases, are Mr. Tyrrell's principal remedies : and no one who has watched his practice at the Eye Infirmary will hesitate to affirm that their results, when pursued with that perseverance, and that steady confidence, which he can communicate from himself to his patients, have in numberless cases been most striking.

It is not to be supposed that no discrimination is necessary to determine the class of cases in which either of these remedies is to be adopted ; but the present work is well adapted to guide every practitioner in his decision in this as well as on many other subjects. In short, the author has done his best to make his reader as good a practitioner as he is himself, and for this he deserves the fullest praise.

We cannot conclude without noticing an unhappy chapter the author has written—that on Strabismus, in which he expresses his confidence in the various popular methods hitherto employed, and his conviction that operative proceedings are unadvisable. His book was published early in the present year. How many thousand times have his former conclusions been practically contradicted by himself as well

as others in the last few months! This, however, is the fault not of the author, who does not possess the power of *prévoyance*, but of the age we live in, and of the industry and rapidity with which novelties are worked out—a rapidity so great, that wisdom must confine itself to saying what is, and leave in silent expectation what is not, probable.

MEDICAL GAZETTE.

Friday, November 6, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

BIRTHS, DEATHS, AND MARRIAGES, IN ENGLAND.

THE second annual report of the Registrar-General of births, deaths, and marriages, in England, is now lying before us. To every thinking man such a document is of value : to the philosophic practitioner it must be of profound interest. He will here see the results of the practice of physic on so large a scale, that he may almost venture to deduce laws from the facts thus forced upon his attention ; or, at any rate, he may prepare the way for the future establishment of truth, by the destruction of favourite errors. These results form no bad corrective to the picked cases usually put forth. A candid and clear-headed correspondent says of the cases which are published in our weekly journals, " I care not what diseases you investigate, if you take the published cases as a fair statement of the results of treatment, you can only come to one conclusion— that the power of medicine and surgery is stupendous ; that its failure is uncommon." But when we come to experience speaking in long figures, how different is the tale ! "Table *(q)* exhibits the progress of four or more epidemic diseases in the metropolis,— measles, typhus hooping-cough, and

scarlatina, which have not yet been effectually controlled by medical science."—Mr. Farr, in Report, p. 98.

The Report commences with a letter addressed to Lord Normanby by Mr. Lister, the Registrar-General.

Several of the points touched upon in it are of great interest.   The mean mortality in England and Wales during the two years 1837-8, and 1838-9, was about one in forty-six : the mortality being less in the latter of the two periods, owing to its comparative exemption from destructive epidemics.

Almost every marriage, says Mr. Lister, is duly registered, and every register of marriage is signed by the persons married : those who cannot write, put their marks. Hence these registers enable us to make a rough guess at the quantum of education which is diffused among the mass of the community, and thus to allay the fears of those praisers of the past time, who lament the spread of knowledge, and who believe, with caricaturists and epigrammatists, that coal-heavers read Byron, and dustmen indite sonnets. Your sorrowful opponent of the march of intellect, before he weeps too bitterly over the fallen state of ignorance, should first ascertain whether it really has fallen so deplorably. There is a pleasant story in the books, that Charles II. wishing to make merry at the expense of the Royal Society, proposed to them the problem, "How is it that a pailful of water is not increased in weight, if a fish be placed on the surface?" Many and various, says the historian, were the solutions offered by the illuminati, until one of the scientific committee, more sceptical than his brethren, proposed to try if the addition of the fish did not actually increase the weight of the pail : to the unspeakable astonishment of his colleagues, it did. The continual deplorements concerning the amazing spread of knowledge admit

of a like answer. Quere, is every one so painfully over-educated as prosers and satirists suppose? Why, no! answer the tables before us; for of 242,166 persons married in the year ending June 30th, 1839, 41 per cent. could not write their names. We must recollect, too, that the great majority of the married were under thirty-five years of age, so that their years of learning fell within the imaginary period of hyper-education.

The proportion of marksmen and markswomen varies extremely in different parts of the kingdom. Thus in Bedfordshire, Monmouthshire, and North and South Wales, the mean of both sexes is, respectively, 60, 61, 58, and 59 per cent. In the metropolis it is 18 per cent., in Cumberland 24, and in Westmorland 27. The small proportion in London may arise from the facility with which the elements of education are obtained here; or, as a contemporary has suggested, from the continual immigration of artisans of the better classes. It is probable, too, that in a city where all the machinery of business is worked so actively, many thousands have discovered that even to sign their names, without any farther clerkly progress, is of itself a valuable accomplishment.

Mr. Lister gives the ages of the parties in 4,858 marriages. They are not selected cases, but are all that occurred in certain districts. There is nothing striking about them, as they agree very well with one's preconceived theories on the subject.

Thus, 158 men and 688 women were married between the ages of fifteen and twenty; 2,536 men and 2,527 women between twenty and twenty-five; 156 men and 134 women between forty and forty-five; 19 men and 6 women between sixty and sixty-five. At every age after twenty the number of men is greater than that of women, excepting

betwen sixty-five and seventy, where we find 4 of each.

The number of buildings in England and Wales registered for the solemnization of marriages, before January 1839, was 1,332; to which 246 were added last year, making a total of 1,578. It is hardly necessary to observe that this list does not include places of worship belonging to the Church of England.

Mr. Lister again mentions a remarkable error which arises from the general disposition of the world to prefer round numbers in uncertain cases. It would appear from the ages at which death took place, as stated in the Population Abstract for 1831, that 30 is a much more fatal age than 29 or 31; 40 than 39 or 41; and so on. As life advances the exact age of the deceased is more and more frequently forgotten; and accordingly the Abstract gives only 25,782 deaths as having happened at fifty-nine years of age, and 26,084 at sixty-one; but 43,273 at sixty. At seventy, 53,953 deaths are supposed by the Abstract, but only 33,038 at sixty-nine, and 32,162 at seventy-one. This Abstract was extracted from the burial registers in England and Wales for eighteen years; so that this remarkable misstatement did not proceed from any temporary cause, but from the habitual inaccuracy of mankind. This error still continues; but it is so obvious, that it is not likely to mislead any one; and, in fact, the tables drawn up for insurance companies have always been formed by taking the mean mortality of quinquennial or decennary periods.

In considering the different portions of the kingdom, "the most marked and serious difference," says the Registrar General, "is that which is observable between the mortality of rural districts, and of large towns, as exemplified in the proportion of the deaths of chil-

dren, and of persons dying at advanced ages."

The greatest proportionate mortality among children is at Manchester, where, of 1000 deaths, 496 were of children under 3 years of age.

But if we add Salford, and the suburbs, to Manchester, the mean deaths are reduced to 475, showing the influence even of suburban air on the rearing of children. In Devonshire this mortality is 296 in 1000; in Dorsetshire and Wiltshire 281; and in some of the northern counties only 253. It is remarkable, and to the beginner in these studies almost inexplicable, that while, in the whole of England and Wales, the mean mortality under 3 years of age was 343 out of 1000, in the metropolis it was only 338. Even allowing for the fact, that half of what is here called the metropolis is suburban, the result is staggering. The hasty statician might infer, that even if Crown Court is not quite so good a nursery as Devonshire, the New Road and Chelsea must be much better than the average of England, so as to make up for the comparative unhealthiness of our central alleys and bye-lanes. But, alas! the terrible perplexity of statistics consists in the difficulty of comprehending every necessary element in our calculation. The probable solution of the problem before us is, that the immigration of adults into London is so considerable, that their deaths necessarily transcend the usual proportion. Their mortality thus masks that of infants, whose unresisting frames sink before the attacks of disease in our crowded and mephitic courts, as the withered leaves of autumn before the east wind!

With respect to the deaths of the aged, the contrast between towns and country districts is still more marked. Thus in Manchester, out of 1000 deaths only 53 were at the age of seventy

and upwards; in Liverpool 60; in the metropolis 99; in the North Riding of Yorkshire, and the agricultural parts of Durham, 202; and in Devonshire, 208. The average for England and Wales is 140.

The first paper in the appendix is a letter to the Registrar-General from Mr. Farr, in which he comments on the causes of death in England and Wales with his usual ability.

The rate of mortality was higher, he observes, in 1838 than in the last half of 1837. Small-pox and typhus prevailed epidemically; and the severe weather, which set in early in January, appears to have increased the fatality of pulmonary diseases.

When discussing the difference of mortality in the two sexes, Mr. Farr observes, that the higher mortality among the males has been attributed exclusively "to intemperance, wars, excessive fatigue, and other external causes;" but he thinks this explanation too narrow, and remarks that the differential mortality is greater before birth, and during early childhood, than in the more advanced ages. There is some justice in this additional explanation, though the old theories seemed sufficient of themselves. Intemperance and hard and unwholesome work are comprehensive categories, and are surely enough to account for a differential mortality of 7 per cent.

We will return to this subject on an early occasion.

CLINICAL LECTURES,

BY W. DAVIDSON, M.D.,

One of the Physicians to the Glasgow Royal Infirmary, and Lecturer on Materia Medica.

ANEURISM OF AORTA.

WE shall now shortly allude to another case, where a peculiar whistle accompanied the sounds of the heart at the time there were few or no bronchitic symptoms; and which

was not observed when these afterwards became very severe; while there was every reason to believe, from the general history of the case, as well as from the stethoscopic signs, that there existed valvular disease of the heart, or some affection of the aorta, or perhaps both.

Samuel Inglis, æt. 18, was admitted on the 11th of July, 1840, with a severe attack of acute rheumatism in several of the large joints of five days' duration. Two years ago he was nine months in this infirmary with rheumatism, and what was believed to be pericarditis, accompanied with effusion; was readmitted for another attack a year ago, and recovered in about three months; after which he enjoyed tolerable health till within a few days before his present admission. His recent attack, in addition to the rheumatic inflammation, was characterised by urgent dyspnœa, palpitation, slight cough, percussion of precordial region extended; impulse of heart increased, seen over a large space, and greatest in cardiac region when in the horizontal posture, but on turning to the left side the impulse was also found to incline more to that side; sounds of heart are loud, and second was accompanied with an acute rasping or filing bruit, which was heard over the greater part of chest anteriorly and posteriorly on both sides of spine, resembling a souffle. There was a circumscribed elevation in left side, about two inches in diameter, nearly two inches below and external to nipple, in which the impulse of heart was very considerable, and which was particularly elevated at each pulsation, resembling a pretty loud whistle, and it seemed to accompany both sounds of the heart. It was most distinctly heard when the patient inclined considerably to the left side; but when he was made to turn to the right it completely disappeared. Both sides of chest measured equally around the cardiac region, viz. $17\frac{1}{2}$ inches. A loud souffle accompanied the pulsations of the abdominal aorta throughout its whole extent. Pulse 100, tolerably full, and jerking. There was no sign, at that period, indicating any particular disease in the lungs, pleura, or bronchiæ. On the 18th of February, that is, about a week after his admission, the whistling sound was gone, and in its place there existed an acute filing bruit, such as is produced by a file acting upon a saw, while the rasp was very loud to the right of left nipple. There was also a change in his decubitus; for on his admission it was on either side, while at this period he could only lay on the left side, and on attempting to turn to the right, and also in changing his position from the sitting to the recumbent posture, an extremely acute lancinating pain was felt in region of heart. There were also numerous sonorous and sibilant rhonchi heard in left

side of chest, and dry crepitation in inferior region of left back, accompanied with the expectoration of a thin glairy mucus. His rheumatic pains were much easier, but the dyspnœa was increased; the pulse more jerking.

March 2d. — Impulse of heart greater about two inches below and to the sternal side of left nipple. Acute filing sound still heard very distinctly in the situation formerly described to be tumefied, but the tumefaction was now gone, although there was still a slight thrill observable, and the sound was inaudible when he turned to the right side. The rasping bruit was heard most distinctly between left nipple and sternum, and also a little inferiorly, and distinctly under left clavicle, but not very loud. It was not perceptible in right chest anteriorly. Pain much less on turning from left to right side, or in shifting his position from the sitting to the recumbent posture. Numerous sonorous and sibilant ronchi are heard nearly over whole chest, and some crepitation in left back. Expectoration a semi-transparent, somewhat tenacious fluid. Pulse 84, moderate, not jerking; tongue white, moist; dyspnœa much less; urine rather scanty; slight salivation. His improvement continued, and he was dismissed on the 20th of April; there being at this time no acute filing sound in the situation formerly alluded to, but in its place there was a distinct sawing murmur; the impulse of heart was much less, although a very considerable jerk was still observable with the eye. He could now lay with ease upon his right side. Pulse 80, rather full, and slightly jerking, and rheumatic pains were entirely gone.

It is quite obvious from the history of this case that the musical sounds which occur in bronchitis had no concern in the production of the peculiar whistling murmur which was heard in a circumscribed spot of our patient's chest; for the bronchitis was very slight during the period that it was audible, and after the inflammation of the bronchial tubes became severe its character was altered. Besides, the holding of the breath, or a suspension of the respiratory process, had no effect in modifying or suspending it. How, then, is the peculiar whistle to be accounted for? The analysis of this case is rendered somewhat obscure from there being two classes of symptoms present; viz., first, those depending on chronic disease of the heart, viz. the rasping bruit, indicating valvular or other disease, perhaps of the aorta, and increased and extended impulse, indicating hypertrophy with dilatation. Second, acute symptoms supervening upon these, after an attack of acute rheumatism, viz. urgent dyspnœa, palpitation, anxious countenance, decubitus on left side, and acute lancinating pain on turning to

right ; a jerking impulse in cardiac parietes, a quick jerking pulse, a circular elevation in left side, where a peculiar whistling, and afterwards an acute filing bruit was heard, and where impulse of heart was very considerable.

Are these last signs sufficient to warrant us in assigning the disease, under which our patient laboured, to be pericarditis or endocarditis? We are inclined to think that both of these affections existed. The whistling and acute filing bruit probably depended on inflammation existing in the left cavity of the heart ; for it was heard only in the extreme left of the cardiac region and was not propagated along the course of the large vessels ; while, when the heart was removed from contact with the ribs of left side, by the patient's turning to right side, the sound was altogether inaudible in any region of the chest. It would seem, from this last circumstance, that the heart either acquired a close proximity to the ribs, for the production of this sound, or that the part of this organ from which it proceeded was so far removed from the sphere of the stethoscope (by the change of position), that it could not be communicated. Upon the whole, then, it appears that musical murmurs in the heart, such as cooing and whistling, may be occasioned by various diseases ; such as, first, disease of the aorta without valvular affection, as in the two first cases detailed ; second, disease of the mitral valve, as in the case related by Dr. Elliotson, and, perhaps, in the case we last detailed ; and, third, in regurgitant disease of the aortic valves, as stated by authors. And need we be astonished that these different diseases should be concerned in the production of musical murmurs, when all of them are ascertained to be productive of cardiac sounds, and when we reflect how the qualities of the murmur must vary according to the size, form, structure, &c. of the diseased parts, as well as according to the greater or less impulse of the fluid which passes over them ?

Diagnosis of Aneurism. — Should the symptoms, in the case first detailed, have warranted us in setting it down as one of aneurism, or one of diseased heart ? There was pretty distinct evidence of hypertrophy ; but, so far as the other symptoms connected with the heart and aorta were concerned, no absolute conclusion could be drawn from them. The rasping and cooing murmur was, no doubt, heard over the larger portion of the chest, both anteriorly and posteriorly, but the impulse was not so great in any situation as in the cardiac region ; the sound was also uniformly double, and not more loud or coarse in the direction of the large vessels. It was, therefore, impossible, from these circumstances, to determine whether

it was valvular, or other disease, probably of the aorta, or aneurism of that vessel. There were several circumstances, however, which, when conjoined with the symptoms enumerated, were calculated to excite a suspicion of aneurism, viz., pain and feeling of weight and constriction in epigastrium, shooting along sternum to top of chest, difficulty of swallowing, and feeling of constriction or obstruction at top of sternum, to which may be added the souffle in abdominal aorta. Authors differ considerably respecting the signs of aortic aneurism.

Dr. Hope considers the following as conclusive of the existence of aneurism :—

" 1. The first aneurismal sound, coinciding with the pulse, is invariably louder than the healthy ventricular sound, and generally than the most considerable bellows murmur.

2. The aneurismal sound, from its source towards the region of the heart, is found to decrease progressively.

3. The second sound actually does sustain this progressive augmentation on advancing towards the heart, &c.

4. Aneurismal pulsation is a deep hoarse tone of short duration, louder than the most considerable bellows murmur of the heart, resembling the rasping of a sounding board from a distance. The bellows murmur of the heart is soft and prolonged, with a gradual swell and fall."

We were unable to verify all of these signs in our patient ; but from this we do not, by any means, intend to insinuate that they are not generally applicable ; for Dr. Hope's powers in the diagnosis of diseases in the chest are well known and acknowledged. The diagnostic symptoms of aneurism, in this case, must have been necessarily very much obscured by two causes ; first, by the loud cooing murmur which accompanied the sounds of the heart ; and, second, the small size and deep seat of the aneurismal tumor must have rendered the sounds less loud than if it had been large and more superficial. The following remarks of Dr. Williams are agreeable to our experience :—" That on the whole, although various circumstances may be taken into account, so as to form a pretty correct opinion, we are still without any of those simple and certain diagnostic marks which may be obtained in other diseases of the chest." The following is a case where the symptoms of aortic aneurism were very distinct, and in which both sounds were louder in the aneurismal tumors than in the region of the heart :—

James Kean, æt. 50, tailor, admitted 16th Oct. 1839, complains of constant and severe pain in front of chest, shooting to back, head, and along arms, accompanied in latter organs by a sense of weight and numbness, palpitation, dyspnœa, which is much increased

on exertion, and occurs in severe paroxysms. Occasional headache, vertigo, hæmoptysis, cramps in muscles of neck, sleep much disturbed; pulse 90, small, and regular; tongue white; bowels regular; skin cool; sweats considerably; decubitus on right side. About middle of sternum, a little to its right side, there is situated a soft pulsating tumor, nearly the size of a walnut, which disappears on pressure, but immediately returns. A similar tumor is situated between the second and third ribs of right side, about an inch from the former. The portions of sternum and rib in the immediate vicinity of tumors seems to be absorbed. The whole of cardiac region is slightly tumefied, and there is extended dulness of percussion in that situation. Sounds of heart in cardiac region are regular, not loud, and sound is accompanied by a very slight souffle. A very strong rough souffle accompanying both sounds, particularly the first, over tumors, at the upper part of sternum and clavicle, particularly over clavicle of right side. A similar sound, though less intense, is heard along carotid, brachial, and femoral arteries, but no perceptible sound is discovered along abdominal aorta. He dates his illness from an inflammatory attack which he laboured under about three years and a half ago. First complained of palpitation, oppression of præcordia, &c. about eighteen months ago, and about a year ago the sternal tumor first made its appearance after great exertion in lifting a heavy weight, and the other in about eight or nine months afterwards.

13th Feb. 1840. — According to the report taken at that time the first sound of tumors is louder, and impulse is greater in left than in right, and in both are stronger than in region of heart. Second sound is pretty similar in both tumors, and appears somewhat louder than in cardiac region. A double rasping souffle is heard nearly over whole of right anterior chest, less distinctly in upper part of left; also very distinctly above right clavicle at top of sternum, but a very slight souffle above left clavicle. A slight double rasp is heard in supra-scapular region, but not distinctly in other parts of back; pulse 68, moderate, and similar in both radial arteries. He was affected with diarrhœa and febrile symptoms, on the 22d February, and, as some slight alteration in the signs occurred, we shall quote the report taken on the 8th March. Sounds in tumor double, are accompanied with a slight souffle, particularly the first, but no rasp, and are both louder than in cardiac region. A rasping bruit, however, was heard at top of sternum and above right clavicle, accompanying first sound. Both sounds of heart were heard in upper part of back near spine, but not accompanied by any murmur; pulse 90,

soft, weak. He now had considerable anasarca of whole body, and was much weaker, and left the house on the 20th April, the anasarca being very great at that time; but the constriction of the chest and impulse of the tumors were rather less.

In this case there are very positive signs of aneurism existing. There are two pulsating tumors towards the right side of the chest, in the region of the arch of the aorta, in both of which there is a strong impulse, greater than that of the heart in cardiac region, and accompanied with a double rasping murmur. The same murmur, but with less impulse, is heard at the top of sternum, above both clavicles, but louder upon the right side. It is also heard double in right supra-scapular region, and a souffle is heard in femoral and brachial arteries. He has also most of the general signs of aneurism, such as pain and constriction of the chest, &c. It may also be remarked that, in this case, the first sound of tumors was much louder and harsher than first sound of heart, and impulse greater, and that the second sound of tumors was somewhat louder than second sound of heart. During the febrile attack, which he laboured under for about ten days in February, the impulse in both tumors, as well as in the cardiac region, was greatly increased, although the rasp was considerably obscured. During its progress, and particularly about its termination, the first formed tumor was observed to be much thinner in its parietes, particularly at its summit, and it communicated to the finger the sensation as if there was nothing but a very thin piece of integument intervening. We have no doubt that the temporary increased action of the heart and arteries had augmented the ulcerative absorption which is constantly going on in such cases, and, if it had continued much longer, would speedily have terminated the patient's life by the bursting of the tumor externally. When, however, the circulation became weaker, both the sounds and impulse of the tumors were much diminished, so that it is probable he may die from the effects of the dropsy and the other disease of the system, before either of the tumors ulcerate externally.

MR. WARBURTON'S BILL.

To the Editor of the Medical Gazette.

Sir,

You will, I am sure, excuse my correcting an error you have, like many others, fallen into, with regard to the circumstance of Messrs. Hawes's and Wakley's names appearing on the back of Mr. Warburton's Medical Bill.

Had we been lawyers instead of medical

men, we should none of us have been puz-
zled at the seeming absurdity of "three
members of the House of Commons agreeing
to bring in jointly a certain measure, and,
before it has even passed its first stage, sepa-
rating and forming three distinct parties."

In order, then, to set this matter straight,
and give to the parties that deserve it the
b'ame or credit attached to the introduc-
tion of this said Medical Profession Bill, the
medical public should be made aware that it
is solely due to Mr. Warburton, and that the
names of Messrs. Hawes and Wakley have
been placed there by Mr. Warburton, because
the forms of the house require that at least
two names should be upon the back of every
bill introduced.

Messrs. Hawes and Wakley have had no
more hand in the contrivance and composi-
tion of this said Bill than his Holiness the
Pope of Rome had, and they have both
publicly declared that they neither of them
saw or heard a line of the Bill until after it
was printed ; so that when, in this week's
GAZETTE, you state that it was brought in
conjointly by the three gentlemen, many of
your readers might (quite unintentionally on
your part) be led into a serious error by
your observations.

Messrs. Hawes's and Wakley's names are
only to be taken as assenting to the general
principle that some reform is required, not
a particle of which, however, is to be disco-
vered in Mr. Warburton's Bill, and had you,
Mr. Editor, had a seat in the House, Mr.
Warburton would very probably have quite
as unceremoniously placed your name upon
the Bill.

How far such a custom in the House of
Commons, as has thus led so many of us into
error, is desirable, it is not for me to decide ;
suffice it to say it is well calculated to puzzle
the brotherhood of " butchers, bakers, and
medical men."—I am, sir,

Your obedient servant,

VERITAS.

London, Nov. 2d, 1840.

[It certainly is calculated to mislead the
uninitiated to find printed on the Bill the
words " Prepared and brought in by Mr.
Warburton, Mr. Wakley, and Mr. Hawes."
However, we readily believe that the two
latter gentlemen had nothing to do with it.—
ED. GAZ.]

OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

IN the last number of your journal you
have inserted a short note of Mr. Lucas's, in
which he says, "that his first operation for

strabismus was performed on April 7th,
1840, &c. and that this operation is the next
earliest on record to these of Professor
Dieffenbach." Words to the same effect
are used in the preface to his treatise, with
the additional vaunt—" whatever merit at-
taches to the fact of being the first surgeon
to perform it in this country, that merit I
humbly yet distinctly claim." Similar
statements are further to be read in the
first and fifth numbers of the Provincial
Medical and Surgical Journal.

Now, sir, these assertions and claims of
Mr. Lucas are in direct variance with the
first report of his cases, which appeared in
the Lancet, April 18th, 1840, from which I
will quote those passages which flatly con-
tradict his present assertion : " The follow-
ing cases prove that British surgeons have
already applied this beautiful and simple
operation to the cure of strabismus." Here-
upon follows the report of Mr. Lucas,
wherein he says, " The success which at-
tended the operations (of Prof. Dieffenbach)
induced me to repeat them on the *first*
occasions which presented themselves to
me." He now relates what he himself dis-
tinctly calls his *Case the first*, and at the
head of the paragraph wherein he describes
the operation he begins with the date *April*
11th, 1840, clearly contradicting his latter
statement as regards the dates.

Mr. Lucas, in a subsequent number of
the Lancet, states that he first became
acquainted with Dieffenbach's new operation
by means of the translation from the Berlin
Medicinische Zeitung, in the British and
Foreign Medical Review for April 1840. I,
on the other hand, read Dieffenbach's origi-
nal account in the beginning of February
1840 ; but certainly did not immediately
proceed to operate upon a human being,
as I wished first to convince myself of cer-
tain points regarding the healing process of
the divided muscles, and of the best and
simplest mode of conducting the operation,
by making my first experiments on animals
and on the dead subject. Thus well pre-
pared, I operated on my two first cases on
April 10th, 1840, and consequently *not*
" experiencing great difficulties in perform-
ing the operation," as Mr. Lucas observes
in his note that he did, I neither then, nor
in any of my subsequent cases, found the
slightest necessity for " the blunt hook for
passing beneath the tendon of the muscle."
My preliminary experiments, together with
my first two cases, were published in the
MEDICAL GAZETTE, April 17th, 1840.

The above facts, based upon publications
appearing immediately after the first per-
formance of the operation in this country,
as well as the testimony in my favour of the
Dublin Med. Press, April 29th, and the
Med. Chirurg. Review, for July 1840, give

clear and decisive evidence against the repeated assertion of Mr. Lucas, now brought forward more than six months after the original statement, and are irrefutable proofs that to my two operations belongs the merit of priority of performance and of publication. The reason why Mr. Lucas now attempts to substitute an earlier date to his first case is very evident ; but such attempts, however often repeated, and however successful they may be with verbal assertions, have no power over printed facts, and can have no weight with the unprejudiced, who, after a fair consideration of facts, judge with accuracy and justice. As you, Mr. Editor, are of the latter class, and if you do not think this note against medical etiquette, I trust to your liberality for its early insertion in your valuable journal,—and remain, sir,

Your obedient servant,

AUGUSTUS FRANZ, M.D.

19, Golden Square,
    Nov. 2, 1840.

VACCINATION FOR A SHILLING.

To the Editor of the Medical Gazette.

SIR,

Now the profession is on the *qui vive*, with reference to the bringing into operation the new Vaccination Bill, I feel every deviation from the ordinary course should be recorded in the public journals. Where I reside, in the parish of St. Mary's, Newington, the Board of Guardians has liberally offered the sum of one shilling per head for vaccination : this you will not feel suprised at, but would you believe that three men, calling themselves respectable members of the profession, have actually come forward and accepted it ? Their names I give (Enoch D. Howitt, 5, Apollo Buildings, Walworth ; Richard Prior, 9, Marlborough Place, Walworth ; William Henry Dry, Trinity Terrace, Dovor Street,) for the benefit of the profession.

I am, sir,

Your obedient servant.

J. T. DARVILL.

7, Dean's Row, Walworth,
    Nov. 3, 1840.

AMMONIA IN DISTILLED WATER.

DR. HERNEFELD has drawn the attention of chemists to the existence of a substance in distilled water, which has hitherto been unknown, though it probably often occurs, viz. carbonate of ammonia. If well-water be used for distillation, that which passes over possesses, as has long been known (especially at the beginning of the distillation), the property of being rendered very turbid by a solution of basic acetate of lead. This turbidity has been ascribed to its containing free carbonic acid ; but it is much more probable that it results from the presence of carbonate of ammonia. Most wells c etain nitrate salts, formed from animal remains deposited on the surface of the earth, and whose soluble constituents gradually sink into the strata of the soil with the rain water, and render the water of the wells impure. Among these soluble constituents is a small portion of nitrate of ammonia, which is decomposed by the double carbonate of lime formed in water during distillation, and passes over with the water.

SALADS.

SALAD herbs are cooling and refreshing. They correct the putrescent tendency of animal food, and are antiscorbutic. Salads are, at any rate, a harmless luxury where they agree with the stomach ; and though they afford little nourishment of themselves, they make a pleasant addition to other aliments, and a graceful appearance on the dinner-table.

Lettuce, of the different sorts, or *salad* as it is often called, is the principal ingredient in those vegetable messes. It should be carefully blanched and eaten young ; when old, its juices become acrimonious and hurtful. Lettuce possesses soporific qualities, and is recommended as a supper article to bad sleepers.

Radishes, when young, are juicy and cooling, but a very few days change their nature, and they become woody and acrid ; when not very young they ought to be scraped.

Cress and *mustard* are cordial and grateful, and of an agreeable pungency ; and *celery*, when young and properly blanched, by its peculiar nutty flavour contributes much to what Evelyn calls " harmony in the composure of a sallet."

A variety of other herbs mingle in full well-selected salads, such as sorrel, young onions, cucumbers, tomatas, endive, radish leaflets, &c. Many wild herbs were formerly employed, and are still used on the continent and in America, as saladings. * * *

Never make a salad till near the dinner-hour, as it will flatten and lose its light appearance by standing. Foreigners call many things salads we would merely reckon cold, little, dressed dishes. As this may produce a confusion of ideas in the young housekeeper we notice it here. Our ancestors had the same notion of what *sallets* were that the French still retain.—*Meg Dods' Cookery.*

RETIREMENT OF DR. CARSWELL FROM UNIVERSITY COLLEGE.

DR. CARSWELL having been appointed physician to the King of the Belgians, has sent in his resignation as Professor of Morbid anatomy in University College, and as Physician to the Hospital. On Dr. Carswell's retirement being known, a large meeting of the students took place, at which it was unanimously voted to present an address to him, expressing their deep regret at the loss of his services, and their admiration of his character as an eminent cultivator of medical science, as a teacher, and as a man.— *Lancet.*

SUCCESSION OF IDEAS.

IT has been supposed by some, that the state of dreaming involves a more rapid course of ideas through the mind ; a vague notion however, as every thing that relates to the εθνος ονειρων seems destined to be, and seemingly incapable of proof. All that we can affirm here is, that the transitions are more frequent and abrupt than in the waking state, when the regulation of the will is present ; and that, as respects rapidity in the succession of thoughts, it is probably as various during sleep as at other times. The evidence of such variation while we are awake is much more decisive. We derive it from consciousness in ourselves, and observation of the minds of others ; and we are frequently able to apply a certain measure to these mental changes by their relation to things without.

One particular topic, rising out of this general view, has not been so much considered, as its interesting nature, and relation to all the mental functions, might have rendered likely. This is the variation in the faculty of the mind of holding one single image, or thought, continuously before it, as the subject of contemplation. The limit to this faculty in all men is certain and obvious, and in most cases narrower than is generally supposed. The persisting retention of the same idea manifestly exhausts the mind, and the effort persevered in beyond a given time does often more speedily dissipate it. But nevertheless, the power as to time is very different in different individuals, is susceptible of cultivation, and, if cultivated, with care not to produce exhaustion in the discipline, becomes a source of some of the highest excellencies of our moral and intellectual nature. It stands contrasted with that desultory and powerless state of mind which is unable to regulate its own workings, or to retain the thought fixedly on points most essential to the objects of it.—*Dr. Holland's Medical Notes and Reflections.*

SPEEDY AND CERTAIN RUBEFACIENT AND VESICANT.

DR. FEHR, of Gundelfingen, frequently uses the following means with a beneficial result :—Bruised cantharides, concentrated acetic acid, and alcohol, of each four ounces. Digest for several days, and strain. The fluid to be applied on linen, or by rubbing.— *Pommers Zeitschrift*, Bd. i. g. H3.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, October 30, 1840.

C. Fox. — D. C. Clark. — W. Goolden. — A. Prichard. — W. Hilbers. — W. Finlay. — R. L. Sleight.—F. S. Cornish.—J. C. Christophers.— F. W. Towle.—F. W. Casson.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, October 29, 1840.

W. C. Freer, Birmingham.— G. E. Stanger, Fleet, Lincolnshire.—T. B. Ireland, Ormskirk, Lancashire.—Thomas Hastings, Longham, Norfolk. — E. O. W. Whitehouse, Liverpool. — R. Counsellor, Durham.—O. Andrews, Canterbury. —J. Trotter, Coleford, Gloucestershire.—Godfrey Saunders, Maidstone, Kent.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, *Latitude* 51° 37′ 32″ N, *Longitude* 0° 3′ 51″ W. *of Greenwich.*

Oct.	THERMOMETER.		BAROMETER.	
Wednesday 28	from 31 to 45		29·10 to 29·28	
Thursday . 29	37	47	29·29	29 32
Friday . . 30	32	51	29·44	29·50
Saturday . 31	36	51	29·50	29·53
Nov.				
Sunday . . 1	33	53	29·58	29·36
Monday . . 2	44	54	29·44	29·50
Tuesday 3	44	55	29·42	29·39

Wind S. on the 28th ; S.E. on the 29th ult. and three following days. The 2d inst. S. in the morning, and S.E. in the afternoon and evening. N.E. on the 3d.

On the 28th generally clear, rain fell during the morning ; the 29th cloudy and frequent showers ; the 30th, morning overcast, otherwise clear ; the 31st ult. generally clear ; the 1st inst. a general overcast, rain in the evening ; the 2d clear, except the morning, rain with boisterous wind ; the 3d generally cloudy.

Rain fallen, ·575 of an inch.

NOVEMBER METEORS. — We have to remind our readers, that the next periodic fall of these phenomena may be expected to take place from the 11th to the 15th of the present month.

NOTICE.

We have to apologize to many correspondents for the delay of their communications. We shall make room for a considerable number of them next week.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture VIII.

Symptoms. Their uses in relation to the diagnosis, the prognosis, and the treatment of diseases. Signs, as distinguished from symptoms. Pathognomonic, commemorative, direct and indirect, symptoms. Examples of symptoms as they consist of uneasy sensations, disordered functions, or changes of sensible qualities.

We are perpetually reading and talking about *symptoms* : and no wonder, for symptoms are the signals by which we learn that disease is present ; the evidence upon which all our art proceeds. We are always, therefore, observing symptoms, analyzing them, striving to interpret their meaning, to ascertain what they signify. Without a knowledge of symptoms we can have no knowledge of the art of physic. Sagacity in penetrating the import of symptoms constitutes a great part of the skill of an able physician. We shall find it useful to take a cursory view of symptomatology, and to familiarize our thoughts with some of the cardinal symptoms themselves, before we speak of them in connection with particular diseases.

What do we mean by a symptom? συμπτωμα—" Something that happens concurrently with something else." Symptoms, they say, are *coincidences,* but this is merely translating the word συμπτωματα into English through the Latin. Symptoms are sometimes defined to be *morbid phænomena*—" any thing observed in a patient out of the course of health." But in forming

our estimate of disease we must often take into account the functions that are natural : these have been said to furnish *negative* symptoms. For my own part, if I were called upon to define a symptom, I should say, " Every thing or circumstance happening in the body of a sick person, and capable of being perceived by himself or others, which can be made to assist our judgment concerning the seat or nature of his disease, its probable course and termination, or its proper treatment : every such thing or circumstance is a *symptom.*"

And it is well that you should take notice at once, that it is for the three purposes just adverted to, that we cultivate the study of symptoms, viz.

First, To ascertain the seat and the nature of the disease under which our patient is labouring : in technical language to form the *diagnosis.* I am no great friend to technical phrases where they can be avoided without inconvenience ; but in some cases short terms of art save us a great deal of tiresome periphrasis and circumlocution.

A *second* object of the study of symptoms is to enable us to foresee and foretel the probable course and issue of the disease ; in other words, to frame the *prognosis.*

And a *third,* and most important use of a knowledge of symptoms, is to direct our *treatment* of the disease.

I suspect that the immense importance of the first mentioned of these three objects— the diagnosis or *recognition* of disease, is not always clearly seen, either by students or practitioners of medicine. Sometimes we are obliged to prescribe for a malady, although we are in great uncertainty, or in total ignorance, in respect to its nature or situation. But this is always unsatisfactory. On the other hand, when we have ascertained where and what the disease is, we apply with much more confidence, and precision, and comfort, those rules for its relief which we have picked up by our own obser-

vation, or have been taught by others. But this is a very limited view of the importance of an exact and true diagnosis. Diagnosis forms the indispensable basis of all *advances* in physic as a practical art. There is a vulgar proverb, that the knowledge of what a disease is, is half its cure. In one sense this may sometimes be true, but in another sense it is not so. Almost all that we know concerning the proper treatment of the sick is *originally* derived from observation, *not* of the *nature of diseases*, but of the *effects of remedies*. That rhubarb will purge, and opium lull to sleep, and loss of blood occasion faintness, are truths which experience alone could suggest, and successive trials alone confirm. They are purely empirical truths. No one could guess them beforehand. No skill in the discrimination of disease has even a tendency to teach them. In some few cases, indeed, we *see* that certain *mechanical* derangements exist, which are manifestly capable of *mechanical* relief. When parts of the body are displaced, as in herniæ and dislocations ; or when distension and pressure are evidently produced by accumulated fluids; the mechanical remedies are at once suggested by the physical and obvious faults. But with such exceptions, diagnosis does not, of itself, afford us *any* direct information as to the cure of diseases ; but it does *this*—it defines and fixes the objects about which observation is to be exercised, and experience collected. When we can once identify a given diseased condition, we obtain the privilege of watching the behaviour of that diseased condition, again and again, under the operation of therapeutic measures ; and from that time the increase of our knowledge concerning the appropriate management of that particular disease becomes progressive and sure. The term experience is obviously misapplied, and the results of all observation are vitiated, when any doubt exists about the sameness of the objects contemplated. It is mainly to this imperfection in the diagnostic part of medicine that we must attribute the uncertainty and variation, both of doctrine and practice, which have brought so much suspicion, and reproach, and ridicule, upon the science we profess. *False* experience, if I may use such a term, has greatly retarded the progress of the healing art : and *false experience* springs from *false diagnosis*. A man will tell you that he has cured a score of cases of advanced phthisis ; but he has deceived himself : they were not cases of true phthisis, but simply cases of chronic inflammation, with puriform discharge, of the mucous membrane of the bronchi. He publishes an account of his success, and of his plan of treatment ; and thus he deceives others also : and thus he retards the science which he fondly and conscientiously believes he is promoting. Accuracy of diagnosis, therefore, cannot be too highly estimated, or too diligently sought after. It has been wonderfully extended within the last twenty years.

The *prognosis*, or foreknowledge of the course and event of diseases, has but little connection with the promotion of medicine as a science ; but it is not on that account less worthy of our attention. Both the physician and his patient find their advantage in the capability of the former to determine whether a disease be remediable—to foresee the changes that may be expected in its progress—to predict the manner in which it will terminate. Knowledge of this kind opens to us a fair and honourable source of credit and reputation ; and it begets a degree of confidence towards us, which is beneficial, not merely to ourselves, but to our patients. Our influence over a sick person, and the efficacy of many of our remedial measures, are remarkably increased by the reliance he places on our skill, and by our apparent acquaintance with the nature of his complaint. It is often of material consequence, in another point of view, that the fatal character of a disease should be plainly perceived. A sick man, aware of his danger, is furnished with a motive and an opportunity for arranging his worldly affairs, in the settlement of which the future comfort and happiness of his family may be very deeply concerned ; for making his will ; and also for more solemn preparation for the awful change that awaits him. For these reasons medical men have, in all periods, endeavoured to read, in the phænomena presented to them by diseases, the event to which those diseases tend. To *form* an accurate opinion on this head is, however, one thing—to *divulge* it another. There is always some risk of losing, as well as of gaining credit, by strong statements or predictions of the death or the recovery of a patient. If you give an unfavourable prognosis, you have a good chance of losing your patient altogether ; his friends argue very naturally, that you are not infallible, that you may be wrong, that if *you* know of no means of safety for him, some other practitioner may, and they *will* grasp at whatever straw comes near them. Do not suppose that this is merely a selfish view of the matter : it is often of much moment to the patient himself, that he should not be tempted to put his life under the charge of impostors, who will feed his hopes, and promise largely, and torture him perhaps with their discipline, and have no mercy upon his pocket. Many an instance have I known of persons dying of consumption, who, when given over by their regular attendants, have been brought to London at considerable expense, to exchange the many comforts of home for the inconveniences of a hired

lodging, that they might be *cured* by that ignorant and cruel and rapacious quack, Mr. St. John Long. There are other reasons, too, why we must sometimes conceal the truth from our patients. It often happens that a person is extremely ill, and in great danger, but yet may recover if he is not informed of his peril. To tell a person in these circumstances that he is likely to die, is to destroy his *chance* of recovery. You kill him if you take away his hope of living. It must be confessed that the duty of the medical man in these cases is very painful and embarrassing: the patient and the patient's friends are urgently inquisitive to know whether there is any danger; or whether he is not yet out of danger. The rule which I have always adopted in circumstances of this distressing kind, when I see clearly that the case is hopeless of cure, is to fix as well as I can upon that person among the family or friends of the patient to whose prudence the real state of the matter may be the most safely confided. If I think that there is a possible chance of recovery, and that a knowledge of his danger by the patient would diminish that chance, of course I urge the necessity of speaking to *him* with assumed cheerfulness and confidence: if I see that the case is absolutely and inevitably mortal, either soon or at some little distance of time, I leave it to the discretion of the person with whom I communicate to disclose or conceal my opinion as he or she may think best. There are, I believe, practitioners, who make it a point, on principles of worldly policy, *never* to speak despairingly of a patient; but I cannot regard such a rule of conduct as honest, or justifiable, or consistent with one's Christian duty.

Now I wish you to observe that symptoms do not serve equally or indifferently the three several purposes that I have spoken of. The same symptom or set of symptoms may indeed at once reveal the nature of the disease, and foreshew its result, and indicate its treatment. When we have discovered what the disease is, we may want no further information to tell us how it will terminate, or how we are to prescribe for it. A man previously sound and well, shivers, then becomes hot, and afterwards sweats, and then reverts to his natural state of comfort and good health: and the same series of phænomena occur every other day. We pronounce the disease to be ague; we predict that, in this climate at least, the patient will recover; and we give him quina; all upon the strength of the same set of symptoms. But this is not necessarily the case: certain symptoms may diclose to us what the malady is, and where it is situated; other symptoms teach us whether our patient is likely to survive or not; and a still different set instruct us what is the proper method of cure to be at-

tempted. We see a number of little pustules scattered over his skin, and we know that our patient is labouring under small-pox. His chance of recovery will be singularly different, according as the spots upon his face run together, or remain separate and distinct from each other. And we investigate the state of his pulse, and his breathing, of his bowels and his brain, before we can venture to prescribe for him. Those symptoms, or combinations of symptoms, which distinguish the place and nature of the disease, we call *signs of disease;* those which teach us what to do, we call *indications of treatment.* We speak also of prognostic *signs.* By keeping these distinct ends of the study of symptoms in mind, we shall be enabled to group them to advantage, and not to huddle confusedly together symptoms that speak, not a different language, but upon a different topic. The ancients, who knew but little of the intimate nature of diseases, but who paid great attention to symptoms, have laid down most admirable rules in respect to prognosis: which shews not only that the prognostic signs are more easily made out, in many cases, than the diagnostic, but also that they may be independent of them.

I have just spoken of *symptoms* as being *signs.* These words are not, however, exactly synonymous, although they are frequently employed as if they were so. Even those medical writers who admit a distinction between them, have not always succeeded in clearly pointing out the difference. Signs are deduced from symptoms, by arranging and comparing them, and noticing the circumstances under which they occur. Symptoms are obvious to all persons alike— to the nurse as well as to the physician: signs, for the most part, are such to medical eyes alone. Let me try to make this plainer by the help of an illustration. Symptoms may be considered as resembling so many *words.* When taken separately, or when put together at random, the words have no force or signification. Arrange them in due order, reduce them into a sentence, and they convey a meaning. The sentence is a *sign* or expression of something which is thus revealed. Symptoms become signs when their import can be interpreted.

A certain crackling sound, of which I shall have much to say hereafter, is heard (we will suppose) in some part of a patient's lung, by the ear applied outside his thorax. This sound is a symptom; any one who listens may perceive it. It is even so far a *sign,* that it denotes the unnatural presence of fluid in the lung, and the passage of air through that fluid. But the fluid may be one of several—mucus, or serum, or pus, or blood: we cannot tell by the sound alone which of these it is. But if we learn that the person in whose lung the sound is audi-

ble has been ill for a day or two only, that he has pain in his chest, cough, embarrassed breathing, and fever, we conclude that he is labouring under that serious disease, *inflammation* of the lung. The crackling sound alone could not assure us of this ; nor without the addition of this sound could the pain, the laboured breathing, the cough, or the fever. Taken altogether, the symptoms constitute a *diagnostic sign*, and bespeak the existence of pneumonia.

Sometimes a symptom, or set of symptoms, becomes a sign, by its relation to what has gone before and what has followed it. To adhere to our illustration, the meaning becomes evident from the context. By comparing, at short intervals, in the supposed case of pneumonia, the extent and character of the sounds heard during respiration, we ascertain whether the disease be advancing or receding ; and thus convert the sounds, or their variations from day to day, into a *prognostic sign*.

We always strive, then, to penetrate beyond the symptoms to the disease of which they are significant. But we do not always succeed in this, and when we do not, (as in the case of ague) we are driven to the necessity of regarding the combination of symptoms as the disease.

You will often hear of *pathognomonic* symptoms. A pathognomonic symptom is one which, when it occurs, settles infallibly the nature of the malady ; becomes a positive *sign* or token of a particular morbid condition. But there are very few symptoms, if there be any, which, taken singly, can ever be said to be strictly pathognomonic signs. But a symptom which in itself possesses little or no value may become very significant when conjoined with others.

Much light is often thrown upon symptoms by what the French call *commemorative circumstances ;* that is, by a knowledge of the previous history and condition of the patient. For example, a person may have palpitation and other marks of disordered action of the heart, and doubts may exist whether these symptoms depend or not upon organic disease of that organ. The question is often determined in the affirmative, by our learning that the patient has had one or more attacks of acute rheumatism of the joints.

There are some other general divisions of symptoms, which it is useful to attend to. Thus some symptoms are said to be *direct*, and others to be *indirect* symptoms. Direct symptoms relate to the very part which is affected ; indirect symptoms are such as " declare themselves through the medium of some other parts, or through the medium of the constitution at large." There are some cases in which the direct symptoms are of much more value than the indirect ; and there are other cases in which those which are indirect are

the most important ; and there are yet many more which require for their elucidation a knowledge of both the direct and the indirect symptoms.

Again, there are many symptoms of which we receive no information, except from the statements made by the patient himself ; and there are many others of which we learn the existence by means of our own observation, by the exercise of our several senses. The relative importance of *these* varies too in different cases. Of course those symptoms which we are able to ascertain for ourselves are the most *trustworthy ;* but both sorts of symptoms shed a mutual light upon each other : we should constantly be making mistakes if we relied solely upon what our patients tell us ; on the other hand, the value of the information we derive from their statements is made apparent by the difficulty we are apt to experience in investigating the diseases of children ; of those who are dumb ; or what is much the same thing, who speak no language that we can understand.

Now, setting aside that notice of the healthy functions which is sometimes necessary in order to determine the relative value and meaning of other symptoms, and regarding those symptoms only which consist of *morbid* changes, they may all be classed under three heads : 1. Uneasy, unnatural, or impaired *sensations :* 2. Disordered or impeded *functions :* and 3. Alterations of structure or of appearance ; changes of sensible qualities. When these last come within the direct cognizance of our senses, they are called, usually, *physical signs*.

Uneasy or altered sensations we can only be aware of through the testimony of the patients themselves. The symptoms belonging to the other classes fall, generally, under our own observation.

Uneasy or altered sensations comprehend a large class of morbid symptoms. By their occurrence persons sometimes become conscious that they are unwell before any other symptoms are observable. Of all the uneasy sensations pain is the most common and the most important. It is very rarely absent in one stage or another of inflammatory disorders ; and it very often occurs, and is very acute too, when there is no inflammation at all. I shall have occasion, in a subsequent lecture, to lay before you the criteria between pains that accompany inflammation and pains that are independent of it. Upon the decision of that point the whole question of treatment commonly depends ; and it is often a most difficult point to decide.

There are many different kinds and degrees of pain. Different kinds of morbid action are accompanied by different kinds of pain ; and the same kind of morbid action, inflammation for example, produces different modi-

fications of pain, according as it affects different parts. The pain that belongs to inflammation of the lungs differs from that which is felt in inflammation of the bowels. Bones, muscles, tendons, ligaments — the bladder, the kidney, the uterus—all modify, in a manner peculiar to themselves, the pain that is produced in them by injury or disease. Different epithets are given to the different varieties of pain—*i. e.* persons endeavour to explain how they feel, by likening their sensations to something which they have felt before, or fancy they have felt. Thus we hear of *sharp* pain—*shooting* pain—*dull* pain—*gnawing* pain—*burning* pain—*tearing* pain—and so on.

When pain is felt in a part, only when it is touched, *i. e.* when *pressure* is made upon it, it is called *tenderness:*—the part is said to be tender. This is a very important kind of pain, as we shall see hereafter. A part may be both painful and tender : or painful without being tender : or tender without being otherwise painful.

Pain often takes place, not in the part really affected by disease, but in some distant part. Inflammation of the liver or diaphragm will cause pain of the right shoulder : the mechanical irritation o a stone in the bladder produces pain at the extremity of the urethra : inflammation of the hip-joint occasions pain in the knee : disease of the heart is often attended with pain running down the left arm : many headaches result from irritation of the stomach. We call these, instances of indirect or sympathetic pain. Some of them admit of no very obvious explanation :— others have been ascribed to connections of the sentient nerves of the two parts—" especially when the part really injured is internal, and that to which the feeling is referred is external, and both derive their sentient nerves from the same larger branches." You will perceive that a due estimation of these sympathetic pains is of no small importance.

I may observe of pain in general, that it is differently felt—or at any rate differently complained of—by persons of different constitutions and temperaments. There are even, I fancy, *national* differences in this respect. I have been present, as you may believe, at a great number of surgical operations, and I have been struck with the different degrees of patience with which the same operation has been borne by Irishmen and by Scotchmen. The Irishman, speaking generally, either feels more acutely, or gives more free vent to his feelings in cries and exclamations : the Scotchman, on the contrary, most commonly preserves a resolute silence. In complaints that are attended with low spirits, and hypochondriacal symptoms, there is reason to believe that the pain spoken of often depends, in a great degree, upon the eager attention that is paid to it.

The accounts given by such patients of their sufferings are always to be received with a grain of allowance ; and this is often an embarrassing circumstance in practice. Patients take it ill if they do not seem to be implicitly credited ; and yet if they are not convinced that much of what they suffer depends on their great attention to it, they will never get well. You will often find that they cease to feel pain—*i. e.* they forget to attend to their complaints — when their attention is otherwise strongly arrested—as by conversation, or music. I adverted to this principle in my last lecture.

Besides pain, in all its modifications, there are many other, and very interesting, uneasy sensations. *Itching* is an uneasy sensation nearly allied to pain. As severe mechanical irritation will cause pain, so a slighter degree of it will cause itching. Itching occurs in many cutaneous diseases, and it gives a name to one of them, which is emphatically called *the itch*. And the Latin word signifying the same sensation, *prurigo*, is made use of to denote other forms of disease of which itching is the most prominent symptom. It often affects some one of the natural outlets of the body ; it occurs about the rectum, from the motions of little worms that nestle in the lower part of that gut. This prurigo podicis, which does not always depend on the cause just mentioned—and the prurigo pudendi in the female—are sometimes most distressing complaints ; harassing the patients continually, preventing sleep, driving them from society, and requiring medical treatment. Acrid matters in the intestines will sometimes produce a kind of itching there ; and the call to void the fæces is perhaps more akin to itching than to any other sensation : sometimes, indeed, it amounts to pain. The tickling often felt in the windpipe, and provoking the person to cough, appears to be of the same nature. Tingling and pricking are sensations which have also some analogy with itching.

Nausea is another uneasy sensation. It is sometimes a *direct* symptom of disease or disorder of the stomach, to which the sensation is referred. Sometimes it is a very important *indirect* symptom, taken in conjunction with others, of disease in some part at a distance from the stomach—in the kidney for example, or in the brain. The nausea which is so troublesome to pregnant women is another instance of a morbid sensation sympathetic of irritation in a distant organ.

Giddiness—vertigo—is another example of an uneasy sensation. It sometimes results from disease within the head ; sometimes it is an indirect consequence of disorder of the stomach ; or of mere debility and an approach to syncope.

Patients will also complain of an undefinable sensation which they usually call

sinking—a sensation which is referred to the epigastric region. This is frequently a source of much distress to hysterical women ; and it is occasionally the fore-runner of death at the close of severe diseases which have a tendency to end fatally in the way of syncope.

Many other symptoms might be mentioned which belong to this class of uneasy sensations, and for our knowledge of the existence of which we must depend upon the accounts given us by the patients themselves. Sensations of weight ; and of tightness and fulness ; drowsiness, tenesmus, strangury, heartburn ; and various depraved conditions of the special senses. In the majority of diseases the appetite is lost or impaired ; but sometimes excessive hunger accompanies and denotes disease. We sometimes form the first suspicion of the existence of diabetes from the preternatural keenness of the appetite. Thirst is a very constant and striking symptom in all febrile and inflammatory disorders ; and in the disease just now mentioned, diabetes, it frequently constitutes the whole distress of which the patient is sensible. The appetite may be perverted, as well as deficient or excessive. Chloroti · girls will eat cinders, sealing wax, slate pencil, and such trash. So women who are pregnant either have or pretend to have inordinate longings for particular kinds of food—longings which are evidently fostered by encouragement. They are not, I believe, common at present in this country ; and among the poor, who have not the means of gratifying them, they are less frequently heard of than in the higher classes of society.

The class of uneasy sensations you see then is a very large one ; and some of the morbid feelings are of very great moment. However, there are not many diseases which consist altogether of uneasy sensations ; and when we find that pain or uneasiness is complained of in any part or organ, we next proceed to enquire whether the *functions* of that part or organ are disturbed or suspended. If we discover any interruption or derangement of function, we have additional reason for concluding that the part so affected in its sensations and in its functions is actually the seat of disease. This is an enquiry which we can prosecute with much less assistance from the patient himself ; and mostly with no assistance at all ; and even in spite of any erroneous notions which he may have formed, and is anxious to state upon the subject. The study of disordered functions is of great practical value.

The functions of the brain and nerves—of the heart and blood-vessels—of the respiratory apparatus — and of the digestive organs—are all of vital consequence.

Some of the impeded or disordered functions which relate to the brain and nerves are in fact identical with the last class of symptoms, and consist of altered or morbid *sensations :* sensation being one of the natural functions of those parts. Depravations, for instance, of the sense of touch ; numbness ; the total absence of sensation, which we call anæsthesia. Symptoms of this kind do not constitute primary diseases, but they often portend or accompany very serious alterations in the brain, or in some part of the nervous system ; and it is from that circumstance that they derive the great interest and importance which belongs to them. The same may be said of perverted conditions of the other senses. The sense of vision is often impaired, and in various ways and degrees, from mere dimness or imperfection of sight, to total blindness. And this total blindness may occur without any other *apparent* disease, the humours and fabric of the eye itself being in all evident respects healthy and right : it may come on, too, so gradually, and increase so slowly, as not to be discovered for a long time, by the patient himself. Mr. Day, the great blacking man, of the firm of Day and Martin, who died not long since, was almost entirely blind. He told me that he first discovered that the sight of one eye was gone, one day when he attempted to look at a distant object through a telescope : he could see nothing, and he imagined that the little brass plate which slides over the eye glass had not been withdrawn. There was, however, no such obstacle ; and he too soon found that when the other eye alone was closed, he was in total darkness. This state of blindness is called amaurosis, and it may depend upon pressure made upon the retina, or upon the optic nerves, or upon the brain at the origin of those nerves. Its approach is sometimes marked by the fallacious appearance of black spots upon the objects the patient is looking at, or floating before him in the air— *muscæ volitantes.* Some of the other depravations of sight are still more extraordinary, and, except that they are not uncommon, might almost be considered fabulous. Thus persons sometimes see things around them apparently in motion, when in truth they are not so. This is, in fact, a symptom I have mentioned before— vertigo : if the patient shuts his eyes, and consequently can see nothing, he feels as if he were himself turning round, while in reality he is at rest : persons in this state fancy sometimes that the bed on which they lie is sinking rapidly down with them into some abyss. A still stranger depravation of the sense of vision is that in which a person sees only one half of an object at which he is steadily looking. One man, in passing along the street, fancied that every body he met had only one eye. The late Dr. Wollaston was subject to this optical delusion ; he frequently found that only one half of the object he looked at was visible : and

he wrote an ingenious paper in the Philosophical Transactions to explain this. After his death a tumor was found in his brain, interfering with the optic nerves. The celebrated Mr. Abernethy had once a temporary affection of the same kind, dependent no doubt upon some slight and transient injury of the brain. He was thrown, I believe, from his horse—at any rate he received a violent blow on his head, which stunned him ; and when he had recovered a little, he was taken home in a hackney-coach. On his way he amused himself with reading the names of the trades-people placed in front of the shops, and he was greatly surprised to find that one half of each name—the last half—seemed blotted out : he described this in his lectures, in his whimsical way, by taking his own name as an example : " I could see as far as the *ne* (said he), but I could not see a bit of the *thy*."

Those very wonderful cases of spectral illusion which sometimes occur, come within the class of symptoms we are now considering : they throw a strong light upon many of the well-authenticated ghost stories —which were in fact mere examples of disease or disorder in the brain of the ghost-seers. It would be out of place to go into any detail upon this interesting subject here. You will find some excellent examples of these spectral illusions in Dr. Hibbert's book on Apparitions, and in Sir David Brewster's Natural Magic, and in Sir W. Scott's Letters on Demonology.

The sense of hearing is liable to analogous disorders. Sometimes it becomes preternaturally acute ; and this is a bad symptom when it does occur. I was called a year or two ago to see a gentleman in the Temple ; he had been taken ill only a few hours before, but I found him dying : the pulse was gone from his wrist, and his skin was cold, but his intellect was entire, and he complained of nothing but of the distress he felt from the loud noises that were made by those around him, in moving about or speaking, although, in fact, all noise was as much as possible avoided, and conversation was carried on in a whisper : but his hearing was painfully acute : he died the same evening ; I believe of an irregular form of cholera. It is always right that patients should be protected from the irritation which might arise from this source ; for that degree of noise which would not interfere with the sleep of a healthy person will often not only prevent it in a sick man, but bring on delirium, and aggravate greatly the disease under which he labours. The custom of strewing the streets with straw before the houses of those who are seriously ill is, in many cases, a very proper precautionary measure.

The opposite fault, *obtuseness* of hearing, is much more common. It often occurs in fever, and it is not thought a bad symptom : it certainly is a much less unfavourable circumstance than morbid acuteness of hearing, and it probably depends upon a disordered state of the brain which is not in itself very dangerous.

What is called *tinnitus aurium* is an instance of the depravation of the sense of hearing. It seems sometimes to result from the too strong throbbing of the arteries. It occurs in many diseases, and is not unfrequently a symptom of diseased cerebral vessels, and a precursor of apoplexy or palsy. It is sometimes in itself extremely annoying. Curious and undefinable sounds are heard by some patients—sounds like a rushing wind, like the falling of a cataract, the noise of a bell, or of a drum. A female patient of mine in the Middlesex Hospital last year, who had disease of the bones of the ear, with symptoms that threatened some implication of the brain ; this patient heard a perpetual noise in her ear like the singing of a tea-kettle. I have lately been consulted by a gentleman from the country, who had no other complaint than a constant hissing, which worried him greatly, in one ear. In a case of spectral illusion related by Sir David Brewster, voices and sentences are said to have been repeatedly heard, when none were uttered.

Affections of the intellect—of what are sometimes called the internal senses, are very common, and very important, symptoms of disease. They are sometimes considered as primary diseases themselves ; they very frequently accompany certain febrile diseases ; and they are not uncommon in diseases that are not attended with fever. There is more or less derangement of the internal senses from the very beginning of continued fever. The power of attention is impaired. That kind and degree of mental exertion which would afford gratification and amusement when we are well, becomes laborious and irksome when we are ill ; and to compel, or to urge the attention, under such circumstances, is injurious. This state is probably only the first degree of delirium, and therefore these slight approaches to derangement of the internal senses are by no means to be disregarded. It is curious that the delirium of fever is always most marked during the night : this seems to be owing to the circumstance that the erroneous notions and wandering thoughts of the patient are not corrected by external impressions made upon his senses. You will find, conformably with the same principle, that your patient sometimes ceases to be delirious upon your visiting him : the sight of a new face rouses him for a time, but he soon relapses.

Voluntary motion is another function connected with the nervous system, and one which affords a great variety of important

symptoms. Like the senses it may be excessive, or deficient, or perverted. Excess of voluntary motion is not common, nor very important. In mania patients sometimes exhibit an extraordinary degree of muscular strength ; indeed, in the delirium of fever something of the same kind may be observed.

But the opposite state, that in which the power of voluntary motion is deficient, muscular debility, is exceedingly common. Debility is an original and essential part of fevers. It appears before there has been time for it to be produced by the exhaustion of disease. It is not always proportional to the other symptoms, and does not necessarily imply any great degree of danger. This sudden and early weakness has been a very striking symptom in our two recent visitations of influenza. Persons previously in apparent good health would be seized as they walked along the street, and be glad to sit down in a shop, or a carriage, and to get home and go to bed. Young and strong persons would be thus prostrated.

In some instances debility does not appear till late in the disease, of which it then forms an important prognostic symptom, and an important guide for our treatment : it shows us that there is a tendency to death by asthenia, and we have to endeavour to keep the patient alive by supporting his strength as well as we can,—this being the chief or the only indication.

Debility is occasionally the principal symptom of the whole disease—as in hemiplegia, paraplegia, or in more partial palsy, palsy of one limb, even of a finger, or of a single muscle, as of the levator palpebrarum. This, though it may seem trifling in itself, is far from being so in reality ; it often forms a fragment only of a most serious disease ; and from such partial symptoms of palsy we may prognosticate a more general and alarming attack. A slight degree of paralysis affecting some of the muscles of the eye will produce a squint, and consequent double vision ; and this occurs not only in hydrocephalus, when it is a most significant phænomenon, but also as a prelude to more extensive palsy. General palsy is sometimes prefaced by an affection of the tongue of the same nature, producing a faultering and indistinctness of speech.

Spasm is an instance of disturbance and the power of perversion of voluntary motion. It consists in an irregular and violent contraction of muscular parts—involuntary, even when the voluntary muscles are concerned. Cramp is a familiar example of it ; and we have been taught, since the cholera has made its appearance among us, to regard cramp as sometimes a very formidable symptom : not formidable in itself, but formidable in respect to the condition that gives rise to it.

Tonic spasm is the principal symptom also of that frightful disease—frightful in its phænomena and in its frequent fatality—tetanus. The convulsions of epilepsy and hysteria, and the jactitation of chorea, are ordinary examples of the perversion of the function of voluntary motion. Sometimes convulsions bode great danger, sometimes none at all.

So also *tremor*, which is nearly akin to spasm, is a sign, frequently, of a morbid state of the greatest peril ; and sometimes it is violent without being attended with the smallest hazard.

If we turn now to the great function of respiration, we shall find that it affords a very great number of morbid symptoms—and those of the highest importance.

Dyspnœa, difficulty of breathing, is one of the most prominent of these symptoms. It may depend upon various causes. In inflammation of the lungs and pleuræ there are several circumstances in operation to render the respiration difficult ; for example, pain, which would be enough of itself ; the effusion of lymph into the texture of the lung, or of serum into the cavity of the pleuræ, mechanically impeding the entrance of the air. In dyspnœa the breathing is almost always most difficult when the patient is lying on his back. One reason for this is plain. In the supine horizontal posture the action of the diaphragm is obstructed by the weight and pressure of the abdominal viscera ; and the erect position obviates this. Upright breathing, *orthopnœa*, has come to be considered as a distinct modification of dyspnœa. The patient cannot lie down.

Sometimes, as in asthma, the difficulty of breathing comes on in separate paroxysms ; the respiration becomes all at once loud, sonorous, and wheezing. A person who had never seen any cases of this kind would imagine that the patient was at the point of death—that it was all over with him ; but the most frightful of these attacks are seldom attended with any *immediate* danger. They depend frequently upon organic disease of the lungs, heart, or aorta : sometimes they seem to be purely spasmodic : sometimes to result from transient congestion of blood in the lungs.

Cough is a violent spasmodic action. A full inspiration is taken ; then the glottis is closed pretty firmly—and in expiration the air is forced suddenly out, and with it, frequently, mucus, or other matters which irritated the lungs or bronchi. It seems to be one of the efforts of nature to expel from the lungs things which ought not to be there. There are several varieties of cough : it is a symptom belonging to so many dangerous complaints—pneumonia, pulmonary consumption, and diseases of the heart—that it always demands strict attention. No one

who has once heard it can ever mistake the *hooping* cough. There is also a startling obstreperous sort of cough, shattering one's ears almost, like the noise of a person coughing through a brass trumpet —which depends upon some peculiar state of the nervous system, implies no danger, and is more distressing to the by-standers than to the person who utters it. I believe you may often distinguish the cough of inflammation of the lungs from that of phthisis, and each from the cough of hysteria, by their respective sounds : but we have much better methods of distinguishing them—viz. the concurrence or the absence of certain other sounds belonging to the respiration, and ascertained by auscultation.

Sneezing is another morbid symptom, which, though it may appear trifling, is not to be overlooked. It is a very common symptom in catarrhal affections. When sneezing occurs in combination with cough, it affords a *presumption* that the cough is not phthisical. Sneezing may even happen as a primary disease, occurring in long-continued paroxysms. I have at present under my care a young lady of an hysterical disposition, whose main distress consists in violent and protracted attacks of sternuta-tion, which have harassed her almost daily for many months. One of our bishops is subject to very inconvenient fits of this kind. He will begin to sneeze and go on sneezing incessantly for a long time together. I be-lieve that he finds an effectual remedy for these attacks in plunging his head into cold water.

I say nothing here of those direct symptoms of pulmonary disease which are ascertained by the sense of hearing—by percussion and auscultation. I shall enter fully into that subject hereafter. A systematic account of symptoms, if this were the fitting place for it, which it is not, would require a dozen or twenty lectures. To perceive the relation of symptoms, taken one by one or in diverse combinations, to the various known forms of disease, you must have some prior know-ledge of diseases. But I am obliged to suppose (however incorrect the supposition may be in respect to some among you) that you are mere beginners, and have still to learn even the rudiments of such knowledge. Different diseases may have many symptoms in common. The same symptom may bear a very different import according as it is combined with other symptoms; or connected with this or that disorder. The proper place for a comprehensive and complete review of symptoms would, therefore, be at the *end* of a course of lectures on the practice of physic. When the various forms of dis-ease had been gone through, in reference to the symptoms belonging to them, then would be the time to take the converse

aspect of the case, and to consider the long list of symptoms in reference to the diseases they denote or accompany. All that I am at present attempting is to give you some general notion of what symptoms are ; to put before you, as samples, a few of the most prominent ; and to shew you, even by this cursory and imperfect view of them, of how great importance it is that we should make their relations to each other and to different diseases, and their signification, diagnostic, prognostic, and therapeutic, the objects of our most diligent attention.

I might find matter for two or three lec-tures—if my present object would admit of them—in the symptoms that are drawn from the functions belonging to the *circula-tion*. Every body knows how much impor-tance is attributed to the state of the pulse. A patient would think us careless and negli-gent if we did not feel his pulse ; and really the information obtained by that little opera-tion is often of the most interesting and instructive kind. But it requires practice and intelligence to appreciate that informa-tion. The qualities that we most attend to in the pulse are its frequency, its regularity, its fulness, and its force. It is necessary that we should know the number of beats which the heart habitually makes in health ; for it varies much in different persons. Its average number of pulsations in a healthy adult is from 70 to 75 ; but there are per-sons who, when they are quite well have always a pulse of 80 or 90 ; and there are others in whom the pulse seldom rises be-yond 60. If we do not inform ourselves of these peculiarities, we may fall into great mistakes. In disease the pulse may acquire a degree of frequency which is scarcely cal-culable ; and the less so because, when it is extremely frequent, it is also extremely feeble : it will reach 150, 160, or even 200 beats in a minute. In other cases—as in apoplexy sometimes, and in some organic affections of the heart—the pulse will become extremely slow. The slowest pulse I ever felt was that of a man sixty-eight years old, who was for some time a patient of mine with diseased heart, and dropsy. His pulse was often as low as 25 in the minute. He died suddenly in his chair, and I was very desirous of examining his body, but his widow would not allow it. In the 17th volume of Duncan's Medical Commentaries, there is a case related in which the pulse was as low as nine beats in the minute. We learn a good deal in certain disorders from the variations and fluctuations of the pulse in respect to frequency—in hydroce-phalus, for example, and in continued fever.

Irregularity of the pulse is another condi-tion which is often full of meaning, and of interest. I hope, as the lectures proceed,

to be able to point out the bearings of these several qualities of the pulse upon our views of disease, and especially upon its treatment. At present I must repeat that I pretend to do no more than furnish you with a few samples of the phænomena that characterise disease. Irregularity of the pulse is natural to some persons. I have a brother who enjoys very good health, and whose pulse is always extremely irregular : I have been told that when he was ill with a fever at school, it became regular. I have heard of several precisely similar cases. There are two varieties of irregular pulse—in one the motions of the artery are unequal in number and force, a few beats being from time to time more rapid and feeble than the rest : in the other variety a pulsation is from time to time entirely left out—the pulse is said to intermit. These two varieties may coincide in the same person, or they may exist independently of each other.

Irregularity of the pulse may be caused by disease within the head—by organic disease of the heart—by simple disorder of the stomach – or it may be merely the result of debility and the prelude of the entire stoppage of the heart's action from asthenia. How important must it be to ascertain and construe each of these meanings of the same symptom. It may indicate mortal disease —it may imply no danger at all : it may afford no clue to any available treatment ; or it may teach us how to ward off impending dissolution.

Another most important quality of the pulse is what is called its hardness, or incompressibility. You find that you can scarcely abolish the pulsation by any degree of pressure ; the blood still forces its way through the artery beneath your finger. Sometimes it is felt to strike a large portion also of the finger, and then we say that the pulse is both hard and full, or large. When it strikes a very small portion of the surface of the finger, it is compared to a thread ; it is a small pulse : and if at the same time it be hard—such a pulse is often described as a wiry pulse. It requires some education of the finger to appreciate with exactness the several varieties of the pulse, even those which are practically important ; for many have been mentioned by authors which are purely fanciful, or useless and unnecessary refinements.

Now this hard pulse I shall soon have to speak of again, in connexion with the treatment required in inflammation. It is one of the best warrants we have, in many cases, of the propriety of bleeding our patient. It does not occur, however, in *all* inflammations, and it may occur when there is *no* inflammation. It may depend upon hypertrophy of the left ventricle of the heart, and then it is beyond the reach of blood-

letting as a remedy. It often seems to be dependent upon a morbid condition of the artery itself, brought on, as Dr. Latham has suggested, by the pernicious habit of dram-drinking. It is, however, at all times considered so much a guide to our practice, that whenever it occurs, it is very necessary that the exact cause of it should be carefully enquired into.

Before I conclude this rough review of symptoms, I must point out one or two that belong to the third class mentioned ; viz. changes of sensible qualities. These include variations in the temperature of the body : in the colour of the surface, and especially of the face : the diminution or increase of bulk ; the latter, when general, we call corpulence ; when partial, swelling : and various other symptoms, especially those which are detected by auscultation.

Wasting, or emaciation, is sometimes the first observable symptom of disease. It occurs in complaints that are not commonly dangerous—as in dyspepsia, and in hypochondriasis, which is often connected with dyspepsia : and when it does appear it marks the reality of the disease. This wasting also happens in many fatal diseases—in phthisis pulmonalis, for example—and in dropsy, although the dropsical enlargement sometimes masks it. It accompanies many acute diseases, and is reckoned an unfavourable symptom ; for it shews that the body is not properly nourished. Sometimes the emaciation is so extreme, that the integuments give way—the bones of the patient are said to come through his skin.

We have examples of symptoms that consist in changes of colour, in the flushed cheek of fever ; in the pallor belonging to many diseases ; in the combination of those colours presented by the red spot surrounded by paleness of the cheek so characteristic of hectic fever ; in the yellowness of the skin and conjunctiva in jaundice ; in the dusky hue of the countenance and the lividity of the lips noticeable whenever the due arterialization of the blood in the lungs is interfered with ; and in a long catalogue of cutaneous disorders.

Let me once more remind you of the peculiar importance of accustoming yourselves to take notice of the symptoms comprised in the last two classes, and especially the last class, that you may attain to a quick perception of them. Changes of sensible qualities speak for themselves, and speak the truth. They cannot deceive us, as the verbal statements of even conscientious patients respecting their uneasy feelings might. They direct us in the choice and order of our questions : nay, they frequently spare us the necessity of putting many questions ; questions which might be irksome or fatiguing to our patients, or offensive to their natural

delicacy, or even hurtful by letting them know our thoughts respecting their disorders. Of the change in sensible qualities we judge by our own eyes, and ears, and fingers, and often by our noses also ; and the change is sometimes, of itself, perfectly characteristic of the complaint.

Many more morbid phænomena, or symptoms, or tokens of disease, might have been mentioned ; but I have said enough, I hope, to rouse your attention to the extent and the fertility of this field of study. When we next meet I shall begin to consider one of the special forms of disease to which all parts of the body are liable—a disease that meets us at every turn—I mean *inflammation*.

EXPERIMENTS

ON THE MOTIONS AND SOUNDS OF THE HEART.

BY THE LONDON COMMITTEES OF THE
BRITISH ASSOCIATION FOR 1838-39,
AND 1839-40.

EXPERIMENTS FOR 1839-40.
[Concluded from p. 191.]

OBS. XXIII.—August 24th. *Subject*— A dog (bull-dog terrier,) one to two years old, stunned, and chest artificially inflated *Phenomena* — Results of threading different parts of the ventricles, and at the same moment pressing the threaded parts with the finger, and pulling at them by means of the thread, shewing the mechanism of the heart's throb.—Rhythm of cardiac and aortic pulsations.—Results of introducing a tube into the cava.—Respiratory suction. — Venous regurgitation in systole.—Phenomena of the heart's action out of the body, both as to motions and sounds.

Section 1.—The heart was laid bare, and a thread was passed through the apex cordis, and a second through the parietes nearly over the mitral orifice, and traction was exerted on each string in a direction outwards and away from or vertical to the point of insertion, and the result was, that in each systole each string was felt to be pulled and rendered tense, and to become lax in diastole. At the moment of tension in each cord, a finger was placed on the point at which each cord respectively had been introduced, and the result was a double sensation, viz. first, that of traction in the cord, indicating contraction of the heart, and mutual approximation of its extremities ; and, secondly, that of outward impulse in the point of the parietes under the finger, indicating, as the reporter conceived, the undulation of the blood reacting against the compressing parietes of the ventricles.

Section 2. — The attachments of the vessels, or muscular parts inserted into the roots of the arteries, especially the pulmonary artery, were observed very distinctly to approximate slightly towards the apex in each systole, and to recede from the apex in diastole.

Section 3.—A barely perceptible difference in time was detected between the systole of the left ventricle and diastole of the aorta ; no distinct interval however.

Section 4.—A glass tube was introduced into the lower cava, and a column of blood obtained, which oscillated frequently, but not in accordance with the heart's motions, but so as to be attributable, the Reporter conceived, to the irregular spasmodic respiratory efforts occurring in the right side of the chest, which was still air-tight the mediastinum being still intact. The oscillations were sometimes short, and rapidly succeeded to each other, with a rhythm not differing greatly from that of the heart, but at other times were protracted through several beats of the heart, viz. an ascent continued for several seconds, successively followed by a descent in the tube of similar duration.

Section 5.—The pulsation of the veins was very distinct to the eye in systole in both the pulmonary veins and cava, but whether owing to the auricular systole exclusively was not examined into with sufficient care. This much was ascertained, that the visible venous action was a diastole coinciding with the commencement of the general action of the heart, and followed immediately by a systole. Neither diastole nor systole of vein seemed gradual, but abrupt and almost instantaneous.

Section 6.—A heavy curved knife was placed on the left ventricle, and held erect between the fingers, so as to allow motion upwards or downwards, and the result was, as in former experiments, an elevation by sudden heave upwards of the knife in systole, followed by a subsidence in diastole, with depression of the surface.

Section 7.—The heart was cut out while still beating, and continued to beat in the hand regularly with normal rhythm for two or three minutes, and notwithstanding being shifted from hand to hand amongst three observers. The first sound was distinct during the whole of the time, but less sharply defined at its commencement. It wanted likewise the jerking motion over the auriventricular openings, and the strong eccentric impulse or upward heaving in systole, and strongly marked subsidence of the ventricle in diastole. The concentric motions and attempt at general rounding and the shortening of the systole were tolerably distinct. There was no second or diastolic sound. When cut open, the columnæ carneæ were seen to act along with the parietes.

Obs. XXIV.—26th and 28th. Repeated the experiment on the contraction of the abdominal muscles, as productive of a sound resembling the systolic sound of the heart, in the presence of Dr. Edwin Harrison, Dr. Hamilton Roe, Mr. Gulliver, Mr. B. Phillips, and Dr. Robert Boyd. The instrument employed was the flexible ear-tube or stethoscope, with which only the experiment is satisfactorily practicable, on account of the strong impulse attending the contraction, and the difficulty of distinguishing the acoustic from the tactual sensations it occasions.

Section 1.— The end of the instrument was placed in contact with the abdominal parietes, and held firmly down upon the surface with the intervention of a shirt and thick flannel undervest. A strong and sudden expiratory effort was then made (in the manner described in the first Report of the London Committee), with the mouth and nostrils closed, so that a strong vibratory action, ending in firm tension of the parietal muscles, was sensible to the subject of observation (the Reporter), and likewise to the observers, and with this result, that a single loud obtuse abrupt short sound was heard, and thought by every gentleman to resemble more or less the systolic sound of the heart.

Section 2.—The same experiment was repeated, with the addition of several folds of silk handkerchief to the intervening substances ; and again with a double fold of cloth and silk likewise in addition to the under clothing above named, but without any important difference of result.

Section 3.—Hard substances also were interposed above the under-clothing, viz. a common framed school slate, and small bound books of different sizes, but no important difference was observed, except with the slate, through which the sound was considered to be less distinct decidedly than in any other form in which the experiment had been tried. In all these trials pains were taken to keep the cup of the stethoscope in accurate contact all round, through the substances interposed, with the abdomen ; and that was easily effected by the use, on the part of the Reporter who was the subject of experiment, of both hands at once in maintaining equal pressure. It is proper to mention that several observers agreed in stating that similar sounds, occurring to them in the cardiac region, would be referred by them to the systole of the heart without any hesitation.

CONCLUSIONS FROM BOTH SERIES OF EXPE- RIMENTS AND OBSERVATIONS, VIZ. THOSE OF 1838-9, AND THOSE OF 1839-40.

Motions.

1. That the order of the motions of the auricles and ventricles is by continuous suc- cession rather than by alternation of actions. The auricles contract abruptly after the rest or pause, and the ventricles immediately after the auricles, without any distinct interval between the successive systoles ; and the diastoles of the cavities follow in somewhat similar order, viz. the auricular diastole coinciding with the ventricular systole, and continuing after ; and the true rest or pause of the heart being constituted by the diastoles of auricles and ventricles together, and in reality, though not in a manner sensible externally, ceasing on the recurrence of the auricular systole : and this rhythm of the motions seems to be universal, and common to warm and cold-blooded animals*.

2. That the visible systolic and diastolic motions are first perceived at the bases or fixed parts of the cavities, viz. in the auricles at the sinuses, and in the ventricles at the fundus cordis, and that the apices of the auricles and ventricles, or free parts, are brought into full action after the other parts, and only just before the supervention of the opposite and next succeeding condition of the cavities respectively, whether that condition be systole or diastole.

3. That in systole the heart is diminished in all its dimensions (except only in such regions or parts of the organs as may have been previously compressed or collapsed, during the unresisting flaccidity of the diastole), and that its long axis in particular is strikingly and invariably shortened.

4. That the normal systolic action of the auricles is energetic and almost instantaneous, and quite universal : the manifestations of contraction in the appendix perceptibly succeeding to those of contraction in the sinus, although by a very minute interval : and that the normal auricular diastole is gradual, continuous, and wholly passive, and is effected by an influx of blood from the cava progressively distending the cavity from sinus to apex, and from the termination of one systole of the cavity to the commencement of the succeeding one.

5. That the systole of the ventricles is gradual in its development, and complex in its phenomena : part of these phenomena being attributable to contraction in the muscular parietes, and part to reaction on the part of the fluids. By the muscular contraction the heart is made to compress the

* The only exception known to the reporter, from books or observation, seems apparent rather than real, viz. an alternation of action, as noted by Lancisi, in the chick *in ovo*, and by several observers, for example, in cases of very rapid cardiac action. In such cases the diastoles have been so hurried and short (owing, no doubt, to very rapid and copious influx from the veins)that the systoles of the ventricles have been closely approximated to each other, and the intervening rest been apparently suppressed, and an apparent alternation of systole and diastole without inter- vening rest been produced.

blood, which resists in all directions alike, and thrusts out the previously flattened, depressed, or collapsed sides of the ventricles, and effectuates in great part that shortening of the organ, that is required to admit of of closure of the auri-ventricular valves : and this reaction of the fluids mainly contributes, under certain favouring circumstances of position, &c. to cause the motion that has been described as tilting of the apex, &c. which motion is principally (the Reporter believes exclusively) a result of the elevation of the long axis of the heart in systole, caused by the assumption of a convex or globular form in the central parts of the organ, instead of the superiorly and inferiorly or laterally compressed state of the previous diastole.

With respect to diastole, it appears that the ventricular diastole or dilatation is wholly passive, exerting no influence over the venous current, or the motions of the arterial valves, and is partly effected by an influx of blood from the veins commencing at the moment of relaxation of the ventricles, and continuing until the succeeding systole, and reinforced immediately before the latter by an abrupt influx from the auricles.

6. That the pulsations of the veins are of two kinds at least in some animals ; viz. both active and passive ; and the latter or passive pulsations, which, on the authority of Haller, may be held to exist in all animals, are attributable to reflux from the auricles in their systole.

7. The præcordial throb or pulsation is caused, immediately, by the undulation of the blood in its resistance to sudden muscular compression in the systole of the ventricles. This reaction of the fluids is first perceived about the fundus of the ventricles, and last about the apex, towards which it seems to be propagated by a continuous undulation from the fundus with extreme rapidity. In consequence of this reaction of the blood, the heart's sides are rendered convex, instead of compressed or flattened as in diastole, and are, in the middle parts more especially, heaved outwards from the central axis abruptly and with great force. Thus on all parts of the surface of the organ an impulse is felt in systole, which is greatest there where, in addition to passive flaccidity of walls, there has been collapse in the diastole (viz. the central parts), and which is least where such collapse has previously been wanting or slight (viz. the apex). This cardiac impulse is usually perceived, in the healthy subject, over the apex only, owing to its being absorbed and neutralized over other parts of the heart by an interposed thick mass of spongy lung.

The heart does not oscillate on the aorta, or move to and fro in the chest from systole to diastole, and *vice versâ ;* nor does it suffer any changes in consequence of its own efforts, and exclusively of movements of the lungs and diaphragm, excepting in its shape and size, and in the thickness and tension of its parietes, and the capacities of its cavities. The doctrine that the præcordial pulsation is caused by a blow received by the ribs, in consequence of the heart's "jumping" (Ἀλμα, Hippocrates) or striking against them ("pectus ferit," Harvey—Costam ictu percutit," Haller, &c. &c.) appears to be superfluous with a view to explanation of phenomena (notwithstanding the ingenious illustrations of the ancient opinion by Senac and Hunter), and to be substantially unfounded in point of fact.

8. That the arterial diastole or pulse, almost every where outside of the pericardium, perceptibly succeeds to the cardiac systole, though near the heart the interval between them is very brief, and, to unpractised observers, difficult to distinguish.

Sounds.

9. That the first sound of the heart depends partly, but in a slight degree, on the abrupt closure and transitory tension of the auri-ventricular valves, which gives to this sound much of its sharp well-defined beginning ; but that the first sound is mainly attributable to cardiac muscular tension alone, and that its prolonged duration is owing in great part to the progressive character of the full systolic effort from fundus to apex ; and that this sound is in no degree attributable to any blow or stroke of the heart against the ribs.

10. That the auricular systole is attended by an intrinsic sound resembling that of the ventricles, but more short, obtuse, and feeble. This auricular systolic sound is often difficult of detection, even on the naked heart, and with tolerably vigorous action of the auricles, owing to its being, to the inexperienced ear, absorbed in, or masked by, the immediately succeeding and much louder systolic ventricular sound.

11. That the sounds of friction in pericarditis may, when well marked and under ordinary circumstances, be expected to be double at least, and they may be not improbably triple or more. In its systole each cavity of the heart moves so as to cause a friction of its attached lamina in one direction against the adjacent lamina of the pericardium ; and in its diastole a pericardial friction is caused by each cavity in an opposite direction ; and as the auricular appendices move to and fro independently of the ventricles, the normal pericardial frictions must be, as direct observation shows them to be, quadruple, or double with the auricles, and double with the ventricles. If, therefore, those frictions were rendered sonorous by the interposition of any rough substances between the rubbing surfaces (as lymph for example), and supposing the heart's actions

sufficiently vigorous, we might, under ordinary circumstances, anticipate with confidence, a duplication of murmurs at least, one systolic and one diastolic. Now this duplication of sounds must be the principal element in the acoustic diagnosis of pericarditis, since effused lymph may be of any thickness, consistence, extent, &c. &c., and may be situate on any portion of the heart's surface between its nearest part and its furthest, and may, therefore, cause friction sounds of the most variable seat, depth, and character. But, of course, another physical means of distinction of great importance remains, viz. the comparatively equable diffusion of the sounds of pericardial friction all around the seat of attrition rather than in any one or exclusive direction.

12. That the sounds of the structurally healthy heart are much liable to modification by deviations from the normal standard in the condition of the fluids, and in the order and force and equability of action of the carneæ columnæ, and other contractile parts governing or influencing the action of the valves and the closure and opening again of the orifices of the ventricles ; and this dependence of the heart's sounds on conditions material or dynamic, wholly excluding structural defect, is so considerable that the second sound may, in the normal heart, for a time be very variously modified, or masked by strange murmurs, or even apparently suppressed, in consequence of hæmorrhage, or from the introduction of poison into the veins : and the first cardiac sound, though never wholly wanting during the active existence of the heart, may still, under similar circumstances to those just referred to, present various abnormal features ; may, ex. gr., be as short as the second sound, or be attended or followed by anomalous murmurs, and be otherwise strikingly modified.

13. Other conclusions, more or less satisfactorily deducible, as the Reporter conceives, from the facts stated, are, that the peculiar sounds occurring in pericarditis, and attributable to pericardial frictions, are not referable only to vascular turgescence, or to abnormal dryness, &c. of the pericardium, but to lymph effused by and adhering to that membrane, or other similar obstacle to the easy and noiseless gliding over each other of the adjacent parts of the pericardium.

14. That the ventricles are of equal capacity during life, and that the inequality usually met with after death is an illusion, as explained long since by Harvey.

15. That the suction influence upon the venous circulation, attributed to inspiration by various writers, is well founded.

16. That the action of the long muscles, and more especially those of the abdominal parietes, is attended with an intrinsic sound.

The notice of this fact by the Reporter has been rendered necessary in consequence of some attempts at verification, and some criticisms on an experiment of the London Committee for 1836-7, published in the last edition of Doctor Hope's excellent work on the Heart.

17. That the sounds of the heart, like the motions, are governed by the same law in all warm-blooded animals hitherto examined, and probably in all kinds whatsoever, viz. that the first sound in all animals is longer and obtuser, and the second sound shorter and sharper ; that those sounds are, as in the human heart, respectively systolic and diastolic ; that their causation likewise follows the same law as those of man, the first sound being mainly muscular, and the second exclusively valvular ; likewise that there is the same causation and mutual relation of the cardiac and arterial pulsations.

(Signed)   JOHN CLENDINNING,
M.D. Oxon. and Edin., Fellow of the Roy. Col. of Physicians, V.P. of the Roy. Med. and Chir. Society, Physician to the St. Marylebone Infirmary.

REPORT OF

PAROCHIAL LYING-IN CASES
(FOR EIGHTEEN MONTHS)
DURING 1839, AND TO THE END OF JUNE, 1840.

By JAMES REID, M.D.
Medical Superintendent of the Parochial Infirmary of St. Giles and St. George, Bloomsbury.

(For the Medical Gazette.)

Puerperal Convulsions, followed by fatal Peritonitis.

CASE IV.   Nov. 23d. -- Catherine M'Carty, æt. 28, a plethoric, stout, thick-set woman, of intemperate habits, came into the Infirmary, in labour with her first child, on the 22d. The membranes had ruptured very early. The os uteri was situated obliquely, and not much dilated, the pains being slight and irregular through the day. As the bowels were constipated, a dose of ol. ricini was given, which operated well. During the morning of the 23d the os uteri, according to the midwife's account, was two inches in diameter, and very rigid ; and at 8 A.M. a strong convulsion took place. 16 ounces of blood were taken from the arm, and she continued sensible during the absence of pain ; but on the return of a very strong one, the convulsions were again brought on. She had about six

attacks. I saw her at 11 A.M. during one of them, and took 16 ounces of blood from the arm again. She recovered after this depletion, and had no return of the convulsive paroxysms. although the pains became of a much stronger character. The os uteri seemed to dilate much more readily after the second bleeding, and the head descended gradually. The infant was born *alive* at half-past 5 P.M. The placenta came away soon afterwards.

She passed urine two hours after delivery, and the bowels were relieved.

24th.—Slept well during the night ; the child being kept away from her. Complains of head-ache ; the nurse imprudently gave her porter, on her asking for it.

Cold lotion to the temples. Mist. Aper.

25th.—Complained in the morning of severe pain in the abdomen, but not preceded by any shivering. 16 ounces of blood were taken from the arm, 12 leeches applied to the abdomen, hot fomentations, and poultices. Great sickness continued through the day. Collapse came on, and she died in the night.

Post mortem examination 27 hours after death.— Abdomen very tumid, and decomposition commencing. On making an incision into the abdomen, a great quantity of turbid fluid, of a brown pinkish colour escaped, with flakes of lymph, and pus-like matter floating in it. The great omentum presented a strong scarlet hue, owing to the highly-injected vessels in it. The small intestines were of a pink colour in most parts, with bright scarlet spots and striæ; in other places they were of a dark red colour. This appearance was chiefly on the sides of the intestines, but not on the anterior part. The large intestines were not much affected. Liver much diseased, presenting the nutmeg appearance so frequently observed in those of intemperate habits. Spleen much enlarged and softened. The uterus was much more healthy in its appearance than we expected, shewing very slight signs of previous inflammation : this, however, is not unusual after puerperal peritonitis. The signs of previous inflammatory action seemed to be confined to the peritoneum.

CASE V. Nov. 22d. — Jane North, æt. 27, first child, of delicate constitu-

tion, was delivered, after a favourable time, of a male child, which died on the 24th. In the night of the 25th the patient complained of severe headache, for which the nurse had merely applied cold lotion.

On the 26th there was pain in the abdomen, but no shivering ; the lochial discharge was stopped, as well as the secretion of milk ; bowels confined. She was ordered fomentations and poultices to the abdomen, and a mild aperient draught.

27th.—I saw her for the first time. She was sitting up in bed combing her hair, and in moving apparently suffered no pain. Her manner was irritable, and the expression of countenance rather unusual and wild. She answered questions clearly, and made no complaints. There seemed to be present a predisposition to puerperal mania rather than to peritonitis. On pressing the abdomen firmly she did not complain of much pain, but I found that in the morning slight pressure alone had been sufficient to cause it.

Hirud. xij. fotus. catapl.

28th.—Pain more severe, but the patient has been sitting up several times.

Rep. Hirud.; Cal. gr. ij., Opii, gr. $\frac{1}{4}$, omni 6 hor.

28th.—Restless. On pressing the abdomen. not much indication of pain. This seems to vary, however.—Continue the pills, &c.

30th.—Found the patient sitting up: she had a wild expression of countenance, but spoke collectedly. Complains of sickness.

Mist. Effervesc.; Morph. Ac. gr. $\frac{1}{4}$. Continue the pills.

Dec. 1st.—For the first time she cannot lie on the right side. The pain is now great on pressure ; complains of intense thirst ; no headache ; wandering in ideas; pulse 160, weak and fluttering: bowels open; urine free. Collapse approaching.

Died on the 2d.

Autopsy 48 hours after death.— Omentum presented a dark purple colour, its vessels being very turgid. A considerable quantity of straw-coloured fluid escaped from the abdomen, containing large flakes of lymph. The cavity of the pelvis was filled by a copious deposition of it, mixed with a yellow purulent matter. Intestines of

a pinkish hue, with marks of inflammatory action on many points: they were not of that vivid colour which was so apparent in M'Carthy's case, but more diffused. Large quantities of pus-like matter and lymph were deposited on every part of them. —Uterus. Peritoneal coat inflamed; vivid red lines and patches on different parts, and this appearance extended to the ovaries and fallopian tubes. The peritoneum generally was inflamed.

After the foregoing cases, the lying-in ward in which they had occurred was cleaned, white-washed, and ventilated. The following case was attended in a distant part of the house, but by an individual who had examined one of the previous cases.

CASE VI.—Betsy Donovan, æt. 25. Third child, delivered on Dec. 3, duration of labour 30 hours; the after-pains strong.

6th.—Seized with violent pain in the middle of the day; abdomen very tense; pulse quick, hard, and small; tongue clean; complains of much pain in the temples, and in abdomen on pressure; no shivering; milk and lochial discharge continuing.

Hirud. xiv. abdom.; Catapl. Lini; M. Febrif.: Cal. gr. ij., Opii, gr. ½.

These remedies relieved her for a time, but at 8 P.M. the pulse had risen, and the pain was more diffused and severe.

Venæsect. ad ʒxvj.

Great relief followed the bleeding, and she slept tolerably well.

7th.—Pain not so severe as yesterday, but if she moves it is much increased. Lies on her back most easily; no headache, but is very thirsty; abdomen is much distended, pain principally about the umbilicus; urine passes freely; bowels open; cold feet; tongue clean; pulse 100, but not full.

Hirud. xxiv. abdom.; Cataplasm; Rep. Pil. Cal. et Opii; hot bottle to feet. Mor. gr. ¼ nocte.

8th.—Much relieved. Slept a great deal during the night; no headache; can lie on either side. Pulse soft and natural; tongue clean.

The patient gradually improved after this.

Peritonitis, followed by Puerperal Mania.

CASE VII.—The following case was the only one which occurred amongst the out-patients, and affords strong evidence of contagion through the medium of a third party. It happened that, on an emergency, the same individual who had attended Donovan, and conveyed, most likely, the contagion to her (as she was at a distant part of the house), likewise officiated in this case, and the same result followed.

Dec. 9th, 1839.—Mrs. Eld, æt. 35, was delivered at 12 P.M. of her ninth child, after a labour of eight hours. In the evening she was attacked with flooding, which, after the loss of a considerable quantity of blood, was arrested.

On the 10th a dose of castor oil was administered.

12th.—When visited was going on very well, but at 9 P.M. had a severe rigor, followed by intense heat.

13th.—Complains of pains in the head and abdomen; the latter is tender on pressure at every part; countenance anxious, and rather pallid; skin hot and dry; pulse 144, hard, strong, and incompressible; bowels not relieved; tongue covered with a thick white fur; complains of great thirst.

V. S. ad ʒxxiv. Cal. gr. ij.; Opii, gr. ⅓, omni 4 hor. Mist. Febrifug. Fotus et Catapl.

The blood was not buffed, but slightly cupped. She was relieved, and the improvement continued till the 15th, when, on the return of pain, she was again bled to ʒxx., and mercurial ointment was applied to the abdomen.

17th.—Salivation; pulse moderate; dejections natural, and pain in abdomen felt only on pressure.—Omit the pills.

18th.—Slight fur on the middle of the tongue only; pain in the left iliac region; irritability of bladder.

Mist. Diaphor. c. Sod. Sesquicarb.

Again improved slowly till the 23d, when she had a relapse, with increase of fever.

V. S. ad ʒxvj.; Ol. Ricini; rep. M. c. Sod.

26th.—Much better, but ptyalism has continued since the 17th.

27th.—Doing well; ptyalism has ceased; no pain in abdomen; appetite is good. Better in every respect.

28th.—At 6 A.M. attacked suddenly with mania; violent and noisy; does

not recognize her friends, but only her medical attendant.

Morph. Acet. gr. $\frac{1}{2}$.

The head was shaved, cold applications kept to it, and a blister applied to the nape of the neck.

Jan. 1st, 1840.—Ulceration of gums and tongue; monomania now only; on all points but one, rational. Tonics and sedatives were administered, but the general health began to give way; and although wine, stout, jellies, &c. were given, a slough formed on the sacrum on the 13th, which separated on the 18th. She gradually sank, and died on the 23d.

This case was under the immediate charge of Mr. Wells, and I attended occasionally only with him. He informs me that the patient had to contend throughout her illness with the depressing effects produced by anticipation of a fatal termination to the labour. This originated from the fact of her mother having died at the same age, and after having borne the same number of children.

After the lying-in ward had been thoroughly cleaned out, the beds changed, &c., the patient, Donovan, by some mismanagement, was removed into it during her convalescence, and after new patients had been admitted and confined. Most probably this circumstance gave rise to the following cases:—

Case VIII.—Emma Keene, æt. 22, delivered of her second child on Dec. 11th, after a lingering labour of fifty-three hours, owing to slight deformity at the brim of pelvis. She had, as I found afterwards, from the midwife, complained of pain in the abdomen on the 13th, but this was relieved by a dose of castor oil.

On the evening of the 14th she was violently sick, but did not complain of pain in the abdomen or head, according to the midwife's account. No shivering

15th.—Vomiting throughout the day of a green bilious matter. Mr. Burgess, the apothecary to the Infirmary, saw her, and ordered an emetic, followed by calomel and opium.

16th.—I was sent for to see the patient to-day for the first time. The sickness was not so constant, but the same green fluid was discharged from the stomach in large quantities. Lo-

chial discharge nearly disappeared. No secretion of milk. Abdomen swollen, but not much pain on pressure, except in the regions of the uterus and liver; the latter was only felt when the pressure was strong. Tongue brown and dry; pulse 120; skin hot; no headache, but her manner was rather flighty; spirits depressed; bowels relieved twice to-day; the evacuations of a green watery character.

Venæsect. ad ʒxvj. Enema. Vesic. reg. hepat. Cal. gr. ij.; Opii. gr. j. omni 4 hor.; Cataplasm.

17th.—Blood highly buffed; sickness relieved somewhat; tongue looks moist: quick pulse; hot skin; pain in abdomen still on pressure; cerebral functions disturbed.

Lochial discharge reappeared slightly last night; urine has passed involuntarily; countenance anxious, and sunk; great thirst.

Hirud. xxiv. abdom. Blister to be dressed with Ung. Hydr. Continue the Calomel and Opium.

18th.—Symptoms much the same.

19th.—Collapse; respiration laborious; wheezing and cough; pulse small and weak. She does not complain of pain. Died at 2 P.M.

Post Mortem. — 21st. Abdominal parietes covered by much adipose matter. Milk oozing from the breasts.

Omentum very much inflamed, and strongly adherent to intestines.

Intestines.—Adhering at numerous points to each other, and covered by a large quantity of flaky lymph and purulent matter; highly inflamed, as well as the peritoneum generally; the vessels injected, and of a scarlet hue, the peritoneal covering of the uterus, as well as of its appendages, bearing more apparent marks of inflammation than in other cases. Very small quantity of serum, however, in the abdominal cavity, in comparison with them. Dark matter oozing from uterus into vagina.

Case IX.—Catherine Donovan, æt. 23, first child, after a labour of thirty-six hours, confined on Dec. 11th, at 8 P.M. On the 18th complained of severe headache and pain in the abdomen, but the latter not increased much on pressure; no shivering; pulse full, and 140. Lochial discharge and the milk likewise free; bowels have been relieved.

Venæsect. ad ʒxiv.; Cataplasm Pil. Cal. c. Opio.

19th.—Blood not cupped or buffed, but serum very opaque; pain relieved.

By the continued use of cataplasms for a day or two, and the exhibition of mild aperients, this patient had no return of her symptoms.

CASE X. — Julia Collins, æt. 20, second child, confined on Dec. 17th, after twenty-four hours' labour. On the night of the 18th had a severe rigor, which lasted for four or five minutes; pulse 130; hot skin, tongue white, and covered with thick fur; no headache; bowels have been relieved. Lies on her back. Pain in abdomen.

Venæs. ad ʒxx.; Cal. gr. vj.; Opii, gr. iss. statim. Catapl.

19th.—Can now lie on her right side; no pain on pressing the abdomen; slept during the night; no sickness. Blood which was taken is not cupped or buffed; skin still hot; pulse 130.

Hirud. xxiv. abdom.   Cal. gr. ij.; Opii, gr. ss. omni 4 hor.

At 9 P.M. feels easy, but complains of a violent craving for food; tongue cleaner; pulse softer and more slow; skin cool; no pain on pressing the abdomen.

20th.—At 7 A.M., complained of pain again in the hypogastric region; pulse 140 and vibrating; tongue dry; eyes rather sunk. Says that the pain is very severe occasionally.

V. S. ad ʒxxiv.; Ung. Hydrarg. femoribus fric. Hirud. xxiv. hypogast. Rep. Pil. Cal. c. Opio.; Morph. Acet. gr. ½ statim. Vesic. abdom. post hirud.

2 P.M.—The blood was highly buffed, and very firm, with the cup-like form; no relief from pain; skin moist, but pulse 136; tongue white and furred; can lie on the left side, but not on the right; cough and difficult respiration.

V. S. ad ʒxvj. Blood slightly buffed.

21st.— Report last night favourable: pulse soft and 100; felt comfortable; slight pain only on pressure; could lie on the right side; tongue more moist; bowels acted several times.

Mr. Wells gave her half a grain of Morph. Ae.

Slept well during the night. Milk has reappeared. Does not feel so well this morning; pain increased; pulse 144; thirst.

V. S. ad ʒxvj.

1 P.M. Only ʒiv. of blood could be obtained. Pain increased; skin hot;

no headache; complains of sudden shooting sensations in abdomen like cramps; great appetite. Urine free; bowels not relaxed; not so much lochial discharge; pulse not hard, but 164; not so thirsty; gums not affected by the mercury.

The small quantity of blood taken this morning very much buffed.

Cal. gr. ij.; Antim. potass. tart. gr. 1-16th; Opii gr. ss. omni bihor.

6 P.M. Sickness at first after the pills, but it·has ceased; pulse hard, full, and 140.

V. S. ad ʒxii.

11 P.M. Felt easier; could lie on left side. Blood last taken highly cupped and buffed; pulse maintaining its frequency; slept for some time.

22nd.—Collapse came on during the night, and she died at 8 A.M. She was quite sensible, and to the last complained of the craving appetite, principally for bread.

Post-Mortem.—23d. Not much serum effused into the cavity of the abdomen; no large flakes of lymph, as in the other cases.

Peritoneum.—Generally only slightly inflamed.

Intestines.—Inflamed in patches: not so generally as in the other cases. The ascending colon adherent by bands to the uterus.

Uterus remaining much enlarged. The peritoneal coat of both ovaries and fallopian tubes, together with the broad ligaments, highly inflamed. The uterus itself, at the junction of the tubes, intensely so. Patches of a dark and livid colour over its anterior surface. Dark matter oozing into the vagina, as in Keene's case.

The midwife who had attended the cases had leave to go out of town for a fortnight. The lying-in ward in which they occurred was again shut up for a month. During this time it was well cleaned, painted, whitewashed, and ventilated. The beds and bedsteads were changed, and the chloride of lime was freely used. Patients were again admitted into it on January 27th, 1840.

CASE XI. — Killick, æt. 25 — first child—confined on the 27th of January, after a labour of 16 hours, at 5 A.M.

On the 29th she complained of pain in the right hypochondriac region: this was accompanied by slight headache; the pulse was quick and rather

hard through the day. Mr. Wells ordered leeches to the abdomen, and the application of a large linseed-meal poultice.

> Mist. Febrif. Efferves. and Calomel combined with Colocynth.

I first saw her on the 30th, at 11 A.M.

Pulse full, but not hard ; tongue furred and dry ; headache. She can bear pressure on the right side, which she was unable to do, I understand, yesterday. There is acute pain now at the epigastric and uterine regions. No shivering, sickness, or thirst. Urine scanty, and likewise the lacteal secretion. She can lie only on her back ; not on either side. Lochial discharge irregular ; bowels opened freely.

The patient was now removed to another ward.

> Twenty-four leeches applied to uterine region. Catapl. Pil. Hydr. gr. v. Opii, gr.⅓. M. 4ta. hor. omni.

11 P.M. Much easier ; pain less ; pulse soft ; skin cool.

31st.—Pulse more frequent, but not hard ; skin warm, and not harsh ; tongue very red, but clean at the edges ; pain much less in the hypochondriac region, but still remains somewhat in the uterine. Bowels relieved ; motions liquid and dark. Lochial discharge scanty ; more thirsty than yesterday.

> Hirud. 24. Cont. remed. alt. Inject. tepid. vagin.

In the afternoon the pain had become more severe ; pulse full and 100 ; tongue dry and brown ; headache.

> Lotio. Refrig. capiti. Mist. Febrif.

8 P.M. Pulse 100, but less full ; head easier ; bowels relaxed ; pain in abdomen less.

Feb. 1st.—Has slept only for a short time during night ; pain slight, but the abdomen much distended ; head free from pain ; tongue very dry ; its edges bright red.

2nd.—Abdomen less tense and painful ; bowels relaxed ; pulse 96 and soft ; tongue more moist and clean. Starts in her sleep.

3d.—Abdomen flaccid, and without pain ; slept tolerably well during the night ; bowels less relaxed ; gums tender. Discontinue the pills.

4. – Slept well ; no pain ; tongue clean ; pulse soft and natural. After this she went on favourably.

Owing to the symptoms presented by the foregoing case, the lying-in ward was again unoccupied for five months, and every precaution used to purify it. At the end of this period it was reopened, and I am happy to say that we have had no return of this formidable disease.

10, Bloomsbury Square,
August 26th, 1840.

ON THE

POSITION OF THE AFTERBIRTH IN THE WOMB,

AND ON THE MANNER OF ASCERTAINING IT BY INSPECTION OF THE SECUNDINES.

BY HUGH CARMICHAEL, M.R.C.I.

One of the Surgeons of the Coombe Lying-in Hospital, Dublin.

To the Editor of the Medical Gazette.

SIR,

In the number of your journal for the 2d of October, you were pleased to publish some observations of mine upon the above subject ; and in that communication I stated that, with your permission, I should on another occasion show that the membranes which envelop the child in the womb, and line its internal surface, retain certain marks upon them, when expelled, corresponding with the part of it each portion of them was applied to ; whereby may be ascertained which was in conjunction with the anterior wall, and which with the posterior, and thus enable us to discover what part of the womb the afterbirth was affixed to, which is known to be firmly implanted upon them.

For the purpose of being better understood, I shall beg leave to repeat here what has been stated by me on a former occasion :—The child in utero is enveloped in a shut sac or cyst of membranes ; in order to escape from which, or get birth, it is obvious that an aperture must be made in it by what is termed the presenting part ; and it is equally obvious that this aperture must be in the part of the membranes which lies over the mouth of the womb. By observing, therefore, the position of the afterbirth relatively with this opening, after the secundines are delivered, we can at once determine how far from the mouth of the uterus it had been. This alone, however, would be insufficient

for the purpose of our present subject. We must go farther, and ascertain where in the vicinity of the outlet of the womb it lay, whether anteriorly, posteriorly, or laterally; and I think I shall be able to shew that this material point can be decided by attentively considering the membranes.

In order to this I must beg attention to the annexed plate, a facsimile of Cloquet's 322d plate, small edition, representing a vertical section of the womb, laterally, so far as the womb itself is concerned, at the full period; Hunter's second plate will likewise serve the same purpose.

Fig. 1.
From this plate it appears that the posterior wall is then straight, or comparatively so; while the anterior one, and the fundus, is very much concave. Hence it must be obvious that the membranes, which are moulded upon the internal surface of the organ, and are, consequently, shaped according to the part of it they lined, take on the same configuration as these two opposite walls, so that the part of them which lay on the posterior one is flat, while that on the anterior is prominent and concave; and further, that they can only assume a smooth uniform surface while in the shape or form so imparted to them, and must become irregular in this respect when

not sustained in that shape, or on any attempt to give them other than it.

For example, as regards the anterior layer, that lined the anterior wall, and therefore concave : so long as this part of them is maintained perfectly distended, or in its natural concave form, so long will the surface there be smooth and uniform : if, however, it lose the support which keeps it in that form, its soft and pliant texture will yield and drop inwards when it is most concave or prominent, assuming there a hollow cup-like shape; and if this part be made tense by extending it in any direction, it will be thrown into longitudinal folds in the direction the extension is made. On the contrary, the part of them which lined the flat posterior wall at once demonstrates a flat configuration upon examination, shewing its natural flat form, taking on a smooth and uniform surface when in that form, and which can only be imparted to the anterior portion of them by throwing them into the distended position. These facts are, I consider, so obvious, that I do not think it necessary to dwell further upon them.

Bearing them in mind, then, let the placenta, with the membranes carefully delivered, so that the latter may, as much as possible, be preserved unbroken, be laid upon a table with its maternal surface downwards : (for this purpose, inasmuch as the membranes are born inverted, of course it is first to be repassed through the opening in them, so that their external surface may be external in the examination). Let the different parts of the membranes be then made successively tight or tense by pulling at the edge of the aperture in them consecutively all round that opening, when it will be found that the appearances above detailed will ensue. Where they are shortest, no matter whether, in the language of captiousness, they be there five inches from the placenta, or but two and a half, they admit of being made smooth and level on their surface by simply extending them. When, however, we come to examine them where they are longest, on distending them here by pulling at their corresponding part of the opening, a different result follows; the membranes sink or dip in the centre, forming a sloping oblong hollow, which is deepest towards the placenta, but gradually lessens or shallows as it

recedes from that to the part of the aperture it is pulled from, and if the tension be increased so as to fully extend the surface here, it is thrown into oblong folds, but cannot be thus made to take on the smooth uniformity of the short part of them.

The evidence afforded by these facts, I think, is obvious.   It is clear that where the membranes are shortest, from the fact of their assuming a flat uniform surface under the above examination, that they there lined a part of the womb, having a similar description of form, the posterior part of it; and that the reason why they dip or hollow in an oblong form and in folds when they are longest, is in consequence of their having there lined a concave surface— the anterior wall.   The greatest depth of this hollowing which is nearest the superior border of the placenta is obviously the part where the fundus lay, and the remainder of it, shallowing gradually off as it approaches the opening in them, represents their position on the less distended anterior surface.

As the placenta, for the reasons I have elsewhere stated, and which I shall presently revert to, generally must lie *laterally* posterior, the part of the dip which points out the lining of the fundus is usually to be found to the right or left of it as it lies transversely before us; and where the membranes were but little broken, so that we could ascertain the axis of the cyst by referring to the breach in them, we have, at the Coombe Hospital, thus sometimes been able to declare in which iliac region the souffle must have existed before delivery: it is almost needless to say, however, that this could only be effected in very favourable conditions of the secundines.

The testimony derived from thus inspecting the membranes will receive additional support from the following fact.   While keeping them on the tension with one hand in the way stated, let pressure be made on them from within with the fingers of the other, and we shall find that where they are longest, and dip or cup as above, they at once yield to the pressure, and bulge out into the distended form they possessed within the womb; the facility of so distinguishing them being greatest at the part nearest the placenta, the part that lined the fundus, and gradually lessening as it approaches

the aperture where they lay within the less prominent part of the front of the womb; whereas, where they are shortest and flat, they resist this pressure, do not swell out, thereby evidently showing this flat shape, corresponding to the posterior part of the womb, to be there their natural configuration.

I believe I need not occupy much time in pointing out the information these facts will give us as to the part of the womb the afterbirth was affixed to. The membranes, having it firmly implanted on them, are generally delivered, or come away unbroken, except as to the aperture above spoken of; its distance from this aperture at once demonstrates its relative position from the mouth of the womb, and by the means here stated being enabled to ascertain the part of the membranes that lined the anterior from that which lined the posterior wall, we can, by observing on which of them it is affixed, or how relatively with regard to the anterior layer, easily and satisfactorily decide whether it was anterior, posterior, or lateral.

It was according to this rule that its position was noted in several hundred instances at the Coombe Lying-in Hospital, Dublin, when it was found to have been posteriorly and laterally placed, at the same time low in that position, in at least ninety-six or ninety-seven times in the hundred.   In my paper upon the placenta I stated this manner of determining its uterine position, only in shorter, but as it appears to me, equally intelligible terms. After observing that the mode of examining the membranes, as pointed out by some of the French authors, would enable us only to determine how far from the fundus the afterbirth lay, I continue : " But by introducing the hand into the opening, we get it into a pouch formed by the membranes, and then by running the fingers along their inside, *opposite* to where they are attached to the placenta, we are at once enabled to perceive by their peculiar appearace *there*, that at *that part* they lined the *anterior*, distended, and concave portion of the womb, and thus consequently fix the back part of it to be the place where the placenta was attached."— *Dublin Medical Journal,* January 1839, p. 463.

This passage I consider could scarcely be misunderstood; nevertheless it ap-

pears it was; for in one of the reviews which appeared in the Dublin Journal against me, it is stated that I offered no proof whatever for assuming the position of the placenta to be as I stated; suggested nothing to enable us to distinguish the anterior from the posterior layer of the membranes: the identical thing which I submit the quotation here given went to. In that reply to my paper the writer observes—"Thus am I able to distinguish the anterior from the posterior part (of the membranes) when removed for examination, a point which I shall afterwards show Mr. Carmichael must have neglected." —*Dublin Journal*, March 1840, p. 20.

And again: "Mr. Carmichael has fallen into a great error in the deductions which he has drawn from their inspection (the membranes). The mistake he has committed must, I suppose, have arisen from neglecting to distinguish the edges of the placenta one from the other, and consequently imagining, that when a short membrane was found at any part, it indicated the mass to have been on the posterior wall. I do not know how else it can be accounted for."—*Ibid.* note, p. 82. I shall make no comment on this mode of criticising.

The result of our investigation, conducted at the Coombe Hospital on the plan here explained, has agreed in every respect with that of Naegele, as far as could be determined by him from stethoscopic inquiry only; the position, with the few exceptions mentioned, has been laterally and posteriorly; sometimes more so, and sometimes less; the inferior edge of the mass extending usually low down. When, however, it is higher up, so that four or five inches of membranes lie below its lower edge, where they are shortest, a better opportunity is then afforded of examining their configuration at that part, so as to determine them there to be flat and level, corresponding to the posterior part of the womb, than when they were but one or two inches.

As I have stated in my original paper upon this subject that I found the placenta generally on the *posterior* wall, it might from thence be supposed I thereby meant the back of the womb directly; that I meant the expression, however, in the signification given in this communication, namely *laterally*

and posteriorly, may be collected from the following passage in that paper.

After observing that the ovum is implanted on the womb near the uterine orifice of the Fallopian tube it traversed, and that the uterus expands to a certain extent at the posterior part of it between the tubes, I continue: "the necessary consequence of this (expansion) is, that in the separation of the tubes from the middle line, the one which gave transmission to the ovum must, to a certain extent, carry it and its placenta along with it, and thus give rise to the fact that the souffle is generally audible in one groin and not in the other."—*Dublin Journal*, January 1839, p. 461.

I have also stated the tubes, one of which I take to be about the centre of the placental attachment generally, to be at the full period laterally posterior, which is a further illustration of my meaning.

The explanation I have ventured to offer as to how the placenta apparently sinks upon the side of the uterus from its first position as pregnancy advances is, that the anterior wall chiefly supplies the increase of the latter organ. I argued that this increase could not take place by all parts of the uterus equally contributing thereto—anterior, posterior, and lateral; for in that case I contended that the part of it which was the fundus on the formation of the placenta, would continue so all through gestation, be the fundus at birth enlarged, and, therefore, that the placenta, which is first formed there, would, at parturition, be found there, and consequently the membranes shew it implanted on them exactly opposite their aperture, or nearly so; whereas, according to the testimony given by the membranes in this respect, and which is certainly indisputable, it is with a very few exceptions indeed found at a very considerable depth on the side of the womb. In the hundred cases investigated in the Brittain Street Hospital, in Dublin, the consideration of which formed the subject of my last communication, the lower edge of the mass is reported in the table of statistics detailing them, to have been within two inches and a half of the aperture in the membranes in sixty-eight instances, in many of which it was only one and a half, or half an inch removed

from it, and three inches in thirteen others, making in all eighty-one out of the hundred, where it apparently shifted from its original position to such a depth on the side of the womb.* In either of these quantities, but particularly the former, this sinking of it as pregnancy advanced must be admitted to have been very considerable indeed. I care not on what side of it the mass was attached, anterior or posterior; if the uterus increased by all parts equally contributing thereto, the fundus rising up uniformly, such a displacement, I contend, could not have occurred, such an apparent sinking towards the os. The fact can only be explained in the way I have suggested, viz. that the side of the womb opposite that to which the placenta is attached must have yielded more than others, and so have furnished a greater proportion to the enlarging of it: how otherwise can it be accounted for? Further, I would insist, if there were no other reason for concluding this table of statistics to be wrong in the evidence it gives with respect to the placenta being found as much on one side of the womb as the other, (see Dublin Medical Journal, March 1840,) it is what may be found admitted in it as to the very low position of it at the full period. The uterine orifice of the fallopian tube, close to which the placenta is first formed, is at or near the fundus when that formation begins; the placental consequently must be there when it is first formed. At the close of gestation the mass is so low on the side as to be nearly seventy times in the hundred within two inches and a half of the aperture of the membranes.

If this sinking of it results from the side of the womb opposite that to which it is found expanding more than the placenta side, and I think it would be difficult otherwise to account for it, and that the evidence this table gives us be correct, namely, that the placenta was found, thus low, as much on one side as the other, it must follow, as a matter of course, that at one time one part of the womb will yield and expand in this way, and at one time another; which I take to be very improbable indeed. I admit the table is perfectly correct so far as relates to the low situation of the afterbirth when parturition arrives, but if any expansion go on in the womb in the way I contend, it must be uniform and regular, and also effected by the operation of some cause, and I think the explanation given in this journal, as to how that can take place on the anterior wall, is not only sufficiently explanatory, but nearly proves it must there occur. I allude to the effect of pressure from the growing child *there*, loosening out its texture, and so preparing it for that purpose.

I have further stated in my paper that if the expansion be effected in the way alluded to, the contractions must take place in a corresponding retrograde direction, so that they likewise shall chiefly go on on the anterior wall. According to this view the fundus before the birth will not be the fundus after the birth; it will then have changed its position, and some other part of the organ occupy its place. I shall conclude these remarks, then, by detailing a matter which bears so much on this point, as to strengthen, I consider, the opinion I have given respecting it, in a very considerable degree.

On the appearance in the Dublin Medical Journal of the table of statistics so often spoken of, the secundines were all carefully delivered and examined at the Coombe Lying-in Hospital, with a view to the noting of the placenta-uterine position with the greatest possible accuracy, and in every instance we found it to have been low on the posterior wall; at least very much removed from the fundus. Pending our proceedings a female died, and an examination of the body after death took place, in which, as may be supposed, the uterus was attentively looked to, when the mark of the placenta was *at* the fundus.

* Of the remaining nineteen, three are reported to have had the placenta at the fundus, (according to Naegele the fundal position occurs but once in the hundred); eleven within four inches of the aperture in the membranes; one within five inches of it; one within six, and in the other three the membranes were so torn that its position in this respect could not be determined. I submit, therefore, that so far as could be ascertained by observation on the membranes made in these hundred cases, with the exception of five, they were all low on the side of the womb. I have asked how can it arrive at this low position if it be first formed at the uterine opening of the fallopian tubes at the second month, unless in the way I suggest? One of these reviews upon my opinions declares the explanation is very easy; it states this occurs *when* the decidua covering these openings yields morbidly before the ovum, and does not keep it up in its proper and natural position. Can such departures, however, from the intent of nature, take place in a proportion of eighty or ninety times out of the hundred? How is this explanation proved, or how has it been discovered?

Now there could be no question but that every placenta delivered in the hospital had been subjected to examination, and among them that which came from this woman. There can, therefore, be no doubt but that in her case its place in utero was *removed* from the fundus; yet examination of the womb itself after death would lead to the supposition that it had been *at* the fundus. To what, then, are we to attribute this discrepancy in the testimony of the two? I think that of the secundines could not be erroneous. In my opinion there is but one way of accounting for it. The contractions of the womb do not take place from the fundus. The fundus does not urge the uterine contents towards the os; these contractions take place in a manner which changes somehow the relative position of the uterine parietes, so that what was somewhere on the side before labour, will be on the fundus after it, and in the case under consideration certainly that somewhere had been on the posterior wall.

In addition to the plate referred to in the foregoing part of this paper, I shall beg to refer here to two more; the first, representing the position of the fallopian tubes, before the womb is enlarged by gestation; and the second, from Hunter's 2d, and Cloquet's 319, plate (small edition) their position at its close: to the latter I would particularly beg attention. I submit it points out their situation then to be "laterally posterior." In the page of explanation adjoining it in Cloquet's work, they are described as "looking or pointing backwards" to the iliac fossæ. "La trompe de Fallope droit, se portant *en arriere*, vers la face interne de l'os iliaque."

Fig. 2.

How, I would ask, then, can they

arrive at that low situation from where the first plate represents them to have been, unless in the way I have described? There is no doubt one mode might for an instant suggest itself, but which a moment's consideration will, I think, shew to be quite untenable, namely, that the fundus expanded between the tubes more than elsewhere, rose up there more than in other parts, and thus had the effect of sinking them upon the uterine tumor. If such, however, were the fact, although they undoubtedly must thus

Fig. 3.
sink on it, still they would there occupy a laterally central position, be directly on the side, whereas they are so much posterior that Cloquet represents them as "looking backwards and into the iliac fossæ." The truth is, there is but one explanation of the matter—the anterior wall chiefly furnishes the supply to the expanding womb.

This second plate will also serve as an elucidation of the nature of one of the arguments used against me in the Dublin Medical Journal, viz. that the fallopian tubes at labour are "*always* to be found *in advance* of the womb," (Dub. Journal, March 1840, p. 32); so much so as, in the opinion of the writer, to call for the special precaution of the operator in performing the Cæsarean section. I believe, however, we need not waste any time in arguing this point of doctrine, with the above plate before us.

Dublin, October, 1840.

TREATMENT OF CYNANCHE.

Sir,

As the principal object of periodical medical works is the advancement of medical science, through the easy publication of practical experience, great praise is due to Mr. Joseph Bell, of Barrhead, for his communication in your Gazette, of the extraordinary efficacy of guaiacum in the cure of cynanche tonsillaris. He has reported six cases taken "at random," as he says, from forty, and so rapidly sanative is it, according to the cases which he has detailed, that no other remedy for the cure of that distressing complaint seems worthy of notice. I have tried it extensively myself for several years, but regret to say, with far less satisfactory result than has fallen to the lot of Mr. Bell. My attention was first drawn to it by my father; and amongst the practical memoranda which he left, (the offspring of nearly 60 years' practice, without one week's absence during the whole of that time!) I find the following observation on the disease in question:—

"Gargles I never prescribe in inflammatory sore-throats. I think they in general irritate, and increase inflammation. Sometimes I have seen a repellent gargle immediately remove the inflammation lower down, and produce cough and inflammation of the lungs: this occurred to me twice in my early practice, and I have never prescribed them since. I prescribe gargles only in aphthæ and putrid sore-throats. In inflammatory sore-throats I frequently prescribe *gum guaiacum* and nitre, thus:

R Gum Guaiac. ʒi.; Mucil. G. Arab. q.s. Nitri ʒi.; Aquæ destillat. ʒvii.; Syrup. Papav. alb. ʒii. Misce. Sumat Cochl. ii. 3tia vel 4ta quâque horâ.

"This practice, I believe, is almost confined to myself, but I have used it often with great success. I was first induced to give it from reading Home's *Principia Medicinæ*, in which he asks 'An specificum sit?' It generally operates on the bowels, and therefore cannot be continued long at a time. I was the more induced to give it from some degree of stimulating similarity to the cayenne always prescribed in sore-throats, even inflammatory, by the West Indians."

As far as my own experience goes I have found the most benefit to arise from free scarification of the inflamed tonsils, leeches to the throat, an emetic in the commencement of the attack, and calomel with purgatives and diaphoretics.—I am, sir,

Your obedient servant,
J. C. BADELEY, M.D. Cantab.

Chelmsford, Nov. 4, 1840.

IRON AND ZINC IN DIABETES.

Sir,

If you think the subjoined case of diabetes mellitus of sufficient interest for insertion in the Medical Gazette, it is at your service.

H. F., æt. 38, an agricultural labourer, called on me for medical attendance towards the close of last March: he was then labouring under considerable debility: the quantity of urine secreted was much more than natural, and an increase had been noticed for two months previous. He complained of a sense of weight at the epigastrium, much increased after taking food: great irregularity in the action of the intestinal tube, with acid eructations; tongue white, and chapped in the centre, with red edges; pulse 84, very feeble: there was no evidence of any previous implication of the lungs, as the stethoscope and percussion gave no signs of any pulmonic disease. I found on examination the quantity of urine voided to amount to 18 pints in 24 hours, of a decided saccharine taste, sp. gr. at 60° 1023; on evaporation more than 6 drs. of solid extract was yielded by a pint, so that about 108 drs. of solid matter was secerned daily. I recommended an increase of meat in his usual diet, and prescribed

R Pil. Opii. Əj. Ext. Hyoscymi. Əj. M. fiant Pilulæ xxiv. Cap. i. ter in die.

This, with attention to diet, diaphoretics (the use of Dover's powder, o.n.) was unavailingly persisted in for some time. Then uva ursi, alum, and catechu, were administered, without any apparent good effect; the disease still progressing. Considering the important action of the sympathetic over the secretions of the digestive apparatus,

and the evident derangement of the whole nervous system, whether primarily or secondarily affected, I determined to make use of the mineral tonics: to that intent I administered

R Ferri Sulphat. ʒi. ; Zinci Sulphat. ʒi. ; Ext. Anthem. Ɔii. M. fiant Pilulæ xxx. cap. i. ter in die.

Under the use of this medicine the symptoms gradually decreased, and in the space of about two months no trace of the disease remained : towards the end of June this man resumed his agricultural occupations, and has not since had any return of his disease.

I am, sir,
Your obedient servant,
E. HOWARD.

TUMOR OF THE PERONEAL NERVE.

By THOMAS GUTTERIDGE, M.R.C.S.

[*For the London Medical Gazette.*]

MR. DOCKER, a hale person, aged sixty-four, was struck on the right leg by a pebble stone about thirty years ago. Severe aching pain was caused by the blow ; and the spot where the injury was sustained, six inches above the ankle, and at the upper margin of the solæus muscle, continued a long time tender. In the course of a twelvemonth a substance was perceived there, which, being pressed, pain shot up the limb. It gradually increased in size ; and about seven years since became much more tender than before. Pressure, whether intentional or accidental, caused pain to dart up to the head, and a shock to be felt through the whole system. The patient said the sensation was precisely that which is felt when the ulnar nerve is pinched at the side of the elbow-joint, only very much more intense. The part of the limb below the seat of injury was quite unaffected, and preserved its full sensibility. There was slight numbness in the tumor after very long walking, but no pain, either then, or at any other time, except as the result of pressure.

In the month of August, of the present year, the tumor was as large as a pullet's egg, and nearly spherical in shape ; it had all the characters of an encysted tumor, and fluctuation could be distinctly felt. It was believed that the distress was caused by the tumor compressing the peroneal nerve, and it was concluded, from its situation beneath the fascia, and partly under the solæus muscle, that no effectual relief could be given without cutting the tumor out. Accordingly, an incision was made, lengthwise with respect to the limb, so as to expose the tumor : its attachments were deep and firm. At the instant of severing the connection at the upper part the patient exclaimed " that's the nerve !" and complained of acute pain : the same sensation, though in a less degree, was experienced at the moment of dividing the lower portion. The wound was closed with plaister, and the limb bandaged and put to rest. Although the adhesive action followed, yet the wound healed slowly : much pain was felt in the parts below the division of the nerve, but none up the limb as formerly. The lower part of the leg and the foot were also very chilly. Altogether there was more disturbance of the health than could have been expected in a person of Mr. D.'s hardy constitution. It was necessary to improve his diet, and particularly to give wine, to counteract a tendency to ulceration at the lower part of the wound ; and he required crutches to enable him to walk. At this time, ten weeks since the operation, he is in good health, and walks upright and firm. The only inconvenience remaining is a feeling of the outer side of the foot being *asleep*, as it is termed, and the consequent uncertainty as to the surface on which it rests : this, however, is diminishing, and the proper sense and natural heat are gradually restored.

The Tumor. — The cyst could easily be stripped off : it was evidently no more than the cellular tissue, condensed, forming the original sheath of the peroneal nerve. This disclosed a substance, egg-shaped, white, smooth, and glistening, and streaked with cream-coloured lines. These lines were plainly the separated filaments of the nerve : they were disposed longitudinally and in regular order, similar to the fibres of an onion. The tumor on being cut asunder presented an appearance not unlike what the vitreous humour of the eye would do if the fine membrane forming its cells could be thickened

and rendered slightly opaque. The fluid contained in the cavities was viscid and lubricious, and being of a straw-coloured tint gave to the section a greenish cast. The enlargement began a quarter of an inch below the point where the nerve was cut across. The filaments here suddenly diverged, and spread equally around. Thus, with the aid of the thickened neurilema, a cyst was formed almost as strong as the sclerotic coat of the eye, which enclosed the structure above described— the deposit in the midst of the nerve. When the tumor was steeped in dilute alcohol it acquired considerable firmness, and an uniform cream-colour throughout.

This case is interesting, as shewing that the nervous cord is exposed to the same casualties as the other parts of the body, and that, on the infliction of violence, it suffers inflammation, and one or other of the natural terminations of that process. In this instance serous effusion into the cellular tissue connecting the nervous fibrils seems to have ensued. The irritation created by walking, together with the accidental bruising and frequent handling of the part, explain how the morbid action was perpetuated. And the appearances go far to account for the extreme tenderness of the part first hurt ; for the pain propagated through the sciatic nerve upward to the brain, where the tumor was compressed ; and also—what is the chief point in the diagnosis—the close resemblance of the tumor of the nerve, the proper neuroma, to an ordinary tumor independent of the nerve, and important to it only from contiguity, and the risk of interference with its functions by pressure.

In reference to this case it may also be remarked that the distinguishing characteristic of neuroma, as noted by Mr. Swan—the free movement of the tumor laterally but not longitudinally— was not clear. In so long a nerve as the peroneal a certain degree of motion might be permitted in the direction of the line of the nerve as well as sideways, (and certainly it was so to some slight extent in this instance), and with regard to the motion laterally, it was here, from the nature of the connections, about equal to that allowed of longitudinally. The conclusion then is (since it is admitted that all the distress that attends neuroma may be produced by

the pressure of an independent tumor on a nerve) that there is not yet fixed any precise and definite test of tumor in the substance of a nerve, as contra-distinguished from tumor in the vicinity of a nerve, and consequently that the surgeon must, as a practical rule, approach cases like the present in uncertainty as to the real seat of disease, and be prepared to remove either the tumor that may intrude upon the nerve, or excise a portion of the nerve itself that may be found to have undergone change, according as exploration with the knife shall enable him to ascertain the condition of the parts.

Birmingham, Oct. 30, 1840.

FRACTURE OF THE RADIUS.

To the Editor of the Medical Gazette.

Sir,

I beg to forward you the following case of fracture of the radius produced by the action of the muscles : you may perhaps think it not unworthy a corner of your valuable publication.

A man, æt. 35, not remarkably muscular, presented himself at the North Dispensary on the 2d of November, with a fracture of the left radius just below the insertion of the pronator radii teres, produced as follows :—He held in his left hand a heavy bar of iron : in twisting his arm into the prone position, in order to place the under suface uppermost upon his anvil, the bone gave way at the point above mentioned.

I am, sir,
Your obedient servant,
H. H. Radcliffe.

Liverpool, Nov. 5th, 1840.

ON THE
OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

Sir,

Should the following remarks be sufficiently interesting, their insertion in an early number of your periodical will oblige.—I am, sir,
Your obedient servant,
C. Radclyffe Hall.

Manchester, Oct. 28, and Nov. 9, 1840.

Although from the number of papers that have lately appeared in connection with the operation for strabismus, a certain degree of ridicule may be at-

tached to one who ventures to add another to the list, yet I trust I shall be freed from the charge of presumption in directing the attention of your readers to a mode of operating more simple, I believe, than any which has hitherto been published. Having operated in the way I am about to describe in ninety cases, since Oct. 3d, I can speak with confidence as to the practicability of the operation, and as it has been approved of by all the surgeons who have seen it performed, and subsequently practised by several, I feel justified in offering it to the notice of the profession.

The patient being seated, and the opposite eye covered with a handkerchief, an assistant elevates the upper eyelid with his finger; the operator sitting in front of the patient, with the little finger of his left hand depresses the lower lid. The patient is then caused to direct his eye upwards and outwards. With a pair of fine forceps the operator takes up a small portion of the conjunctiva at the distance of about a quarter of an inch from the nasal margin, and rather below a line drawn from the inferior margin, of the cornea. With a pair of curved scissars, previously held in the right hand, this bit of conjunctiva is snipped off. Through the aperture thus made in the conjunctiva, the lower probe-pointed blade (of which the concave is the cutting edge) is passed along the sclerotic: being kept close to the globe, it is directed backwards and rather downwards: the upper eyelid is now allowed to fall, by depressing the handle of the lower blade: its probe-point rises upwards between the tendon of the internal rectus and the eyeball, causing a slight projection of the upper part of the conjunctiva. With his left hand the operator raises the upper lid *before* he draws the tendon forwards; then gently drawing towards him, the tendon is seen as a white opaque band across the blade, covered, together with the probe-point of the instrument, by conjunctiva. Closure of the blades, by dividing conjunctiva and tendon together, completes the operation. One pair of scissars and a forceps being the only instruments used, I think the operation can scarcely be more simplified.

Notwithstanding your late correspondent, " Speculum," strongly deprecates the attempt to operate on children,

without using some instrumental means for fixing the eye, I experienced no difficulty in operating as above on a boy three years and a half old. I tried with the speculum in one instance, but found it much more in the way than the finger of an assistant. Of hooks of all kinds, as they certainly increase the pain, and injure more or less the sclerotica and conjunctiva, if they can be dispensed with, no argument against their use seems required.

In seventeen cases I completed the operation without any assistance, except from a person holding the head firm, separating the lids, and using the forceps with my left hand; and this is less formidable to the patient than any other mode of procedure. To succeed satisfactorily, however, the patient should be calm and steady, and the eye large, and not particularly irritable.

When the patient is much frightened and restive, and squeezes the eyelids strongly together, it is easier to pass a small steel probe, bent near the end at a very obtuse angle, through the opening in the conjunctiva beneath the tendon, and then, persuading the patient to open his eye voluntarily, to bring the tendon forwards, hitch the margin of the upper lid over the prominence formed by the end of the probe, and then to pass the lower blade of the scissars along the side of the steel probe. The probe is not larger at the end than elsewhere, is not grooved, and is fixed in a common scalpel handle. It is also useful to seek out and bring forwards the fibres which adhere far back, if the inversion still remains after the more superficial band of tendon has been divided.

I believe I may assume for this mode of dividing the rectus internus oculi the following advantages :— Simplicity, from the few instruments required; facility and rapidity with which it may be performed, (a surgeon who was present told me that in one case the operation was completed in twenty seconds); freedom from hæmorrhage and puffiness of the part until after the division of the tendon ; as small a wound as possible ; very much less pain than when the conjunctiva is first dissected off the tendon ; impossibility of doing injury to the eye, should the patient prove unsteady, and, as sometimes has happened, snatch the instrument violently away.

The after-progress of the cases has

been in every respect satisfactory ; and I may here mention the advantage derived from closing the eyelid by strips of gold-beater's skin or court-plaster. There is less sprouting of the granulations, and any ecchymosis disappears more rapidly than when wetted lint merely has been applied. I am indebted for the hint to Mr. Hunt.

The scissars I use are rather large, the blades being when closed an inch and a half in length ; the curve is at first very slight, near the end rather greater. The probe-point on the end of the lowest blade is very small ; the concave cutting edge is fine; every other edge smoothly rounded off. The upper blade is one-sixteenth of an inch shorter, and its convex edge is sharp to its extremity. Unless the blades close with the utmost accuracy, and are very well set, they will not divide the structures by one cut.

To any one about to repeat the operation I have described, the following remarks may not appear impertinent :— The chair should have a high back, against which the patient's head can be firmly held, so as to preclude any sudden jerk backwards. The opposite eye should be covered effectually, or the squinting eye cannot be directed sufficiently outwards, or *vice versâ*, and the difficulty of keeping the eyelids apart will be greater. The snip in the conjunctiva should not be made too high, or too far from the cornea, or the cellular tissue between the internal rectus and the wall of the orbit alone will be brought forward. The probe-pointed blade should be pushed far enough back into the orbit before its point is elevated, there being nothing which can suffer injury from so doing. The sense of resistance when the tendon is felt, and the audible snap which often accompanies its division, are very characteristic.

<div style="text-align:center">

OBSERVATIONS

ON THE

PATHOLOGY OF STRABISMUS.

By Edward Hocken, Esq.

(For the London Medical Gazette.)

</div>

It is a fact, well proved by repeated observation, that there exists a tendency, both in double and single strabismus, for the eye either not affected at all, or much less so than the other, to assume the degree and extent of the squint which previously existed in the other, when the sound eye is covered, and the squinting eye is called into exercise.

This mutation of the strabismus from the deranged to the previously healthy eye (I am now speaking of single strabismus) is a peculiarity well worthy of note. The sound eye is covered, whilst the distorted eye is employed, and we find that there is either an immediate change, or that this change is not effected until the originally normal organ has been bound up for some time ; but that this tendency exists in every case, to a greater or less extent, provided that the strabismus have been of some duration. I would inquire how is this effected ? Perhaps this may be the explanation : the organs have been acting irregularly for a length of time, without that due degree of connection and consent which ought to subsist, and to this they have become habituated, so that they turn constantly, having the same relation to each other in their abnormal condition as they previously moved in harmony during their healthy state ; hence, when the proper direction is temporarily given to the squinting eye, the organ originally healthy has an inclination still to hold the same relation to that eye as it did whilst affected with strabismus, and is turned out of its healthy axis in obedience to this impulse.

If this explanation be true, then it would apply also to the cure of strabismus by operation ; here, for some time, there would be a tendency in the opposite eye to assume the squint. That such is the case I am perfectly convinced, not only in double but single strabismus. These are my proofs :— a gentleman, in whom the squint was single, and in whose other eye there was no immediate tendency to assume an abnormal direction, on covering the organ and calling the squinting eye into action, was operated on for the complaint ; the operation was at first successful, and the squinting eye was directed healthily ; but after some days the previously healthy eye began to assume the squint, and shortly afterwards became affected with strabismus, in an equal degree to the originally maldirected organ.

Mr. B. Lucas, in his excellent little "Treatise" on strabismus, states that, even in those cases which he denominates single, namely, those in which there exists no immediate tendency to the transfer of the squint, he has seen, in several instances, the eye which was not operated upon have a slight inclination inwards for several days after the operation; but, when the healing process was completed, and both eyes were freely exercised by the patient, this inclination inwards gradually became less and less (p. 49). On this subject we may also consult the experience of MM. Guérin and Roux.

Now it becomes of importance to trace the difference between single and double strabismus, since it has been made a question whether single strabismus ever occurs; whilst, on the contrary, we find some authors asserting that it is always single, and that consequently double strabismus does not exist.

Mr. Elliot, in the Lancet for Sept. 12, came to the conclusion "that the strabismus could not be regarded as confined to one eye." His reason for this conclusion was founded on the fact, that, when the sound eye was closed, the affected one became straight; but on raising the lid of the former it was found inverted, though the position of the eyes was soon reversed again. I shall presently allude to this subject, in order to ascertain what constitutes double strabismus. From the Lancet we will turn to the Dublin Medical Press; and here we shall find Mr. Crommelink stating, from an enlarged opportunity of practical experience, that he is disposed to support the opinion of Buffon, namely, "that strabismus never affects both eyes simultaneously;" this decision having for its foundation the results of the operation. He tells us that where one eye is much affected, the other, no doubt, at first sight, seems equally so; but when the distorted eye is restored to its natural position by the operation, the opposite eye loses its apparent deviation, either immediately or after a short time. My belief is, that both these opinions are incorrect, and that strabismus occurs single—confined to one eye, and also as a double lesion, when both eyes are concerned.

By what symptoms do we diagnosticate double and single strabismus?

Mr. Bennett Lucas, in his work, previously alluded to, page 49, directs us to form our diagnosis by placing the hand obliquely over the eye, in such a manner as to hide all objects in front of it, but kept sufficiently raised at the temporal margin of the orbit to enable us to watch its movements. The patient is directed to exercise the eye which is uncovered; and if, at the time that he brings it to the centre of the orbit, the covered eye retreats into the inner canthus, the case is one of double convergent strabismus, and both eyes will require to be operated upon; but if both eyes are at this period straight, or even if the covered eye has but a slight inclination inwards, the case is one of single convergent strabismus, and the inner rectus muscle of one eye only will require to be divided.

The practical deduction from this reasoning is evidently most excellent as a general rule, but I believe with some exceptions; I must differ, however, somewhat in the determination of those cases which are, and those cases which are not, double. To judge of the presence of double strabismus we must be guided by the appearance of the eyes themselves, for here both organs are habitually (or both are, during the continuance of the squint) turned out of their normal axis; this, during the ordinary employment of the organs, is especially evident in one, but from a variety of circumstances may change in intensity from eye to eye; yet still, under all circumstances, both globes, not one, are morbidly directed.

The tendency still to hold the same relative situation to each other exists in all cases, double or single: how far double strabismus is dependent on this tendency becoming increased and habituated, whilst the originally squinting eye becomes more and more abnormally situated, I cannot say; but I think it probable that every case is primarily single, and, therefore, that this, in conjunction with the original exciting cause, is the most likely explanation of its formation. It is therefore probable that they are intimately connected; but still I maintain that where the squint, in ordinary vision, is habitually confined to one eye, that that case has no title whatever to the name of double strabismus, and this whether there be an immediate or a slower transfer on binding up or

covering the opposite eye ; the one being merely a more developed degree of the other.

From a due consideration of the subject, therefore, we may deduce that it would be necessary to warn patients of this tendency of transfer in the strabismus from the eye which may be operated upon, to its fellow; and this especially in true cases of double squint, and in those where there exists a strong tendency to assume the same relation to the true squinting eye as the healthy eye did whilst abnormally directed. Should a transfer occur, and should it resist mild measures, such as gentle employment of both and each organ, together or separately, the squint becoming permanent, then the operation must be repeated on the opposite eye.

As regards the actual condition of the muscles in strabismus, I stated in a recent paper (p. 943), that in many severe and long-continued cases, where excessive muscular action was induced, hypertrophy of the muscle so acting had eventually supervened; and that in all cases, whatever their remote pathology, the actual local condition was always either excessive or deficient innervation, or excessive muscular action of primary origin. For particulars I must refer to the paper itself. I mention this subject, since it has been alluded to by Mr. Duffin, in a paper which appeared last week. He says, " I am not prepared to assert that such a change in the development of the muscles of the eye never exists, though I do not believe it to be the general condition of the inner muscle in cases of this description." Judging from analogy of what we observe to occur in other parts, under similar circumstances, we should say that this must be the frequent consequence of habitual strabismus. It would take place in all cases where excessive muscular action was the primary lesion; but how long the affection might remain as mere spasm (permanent contraction from excess of innervation), from derangements or diseases of the general nervous system, brain, or abdominal viscera, I will not pretend to say. But it is evident that hypertrophy must be a frequent termination, since excessive muscular action in other parts, if long continued, invariably leads to this result; whilst, on the contrary, parts

not subjected to their proper employment, become debilitated in their functions, and atrophied in their structure. Hypertrophy would not occur in those cases where the squint resulted from deficient action of some muscles, the healthy direction being disturbed by normal action in their opponents simply, nor in any case where the vital attraction between the capillaries and muscular tissue was not unduly augmented. Here, perhaps, I may add congenital cases (which are very rare), depending on original deformity, or congenital shortening, &c., of the muscle or muscles.

Most pathologists who have written on strabismus confirm these statements: thus we find Mr. Middlemore stating that in a case of divergent strabismus, examined by him, the external rectus of the eye affected with strabismus was much larger than it ought to have been—much larger relatively to the size of the other muscles of the same eye, and comparatively, with those of the opposite organ. "Other circumstances," he says, " may induce a disproportion in the form and power of the muscles of the eyeball, and will lead to the establishment of a variety and extent of strabismus, corresponding to such changes."

Mr. B. Lucas informs us that he has had many opportunities of witnessing the great development of the inner rectus muscle in convergent strabismus, and that many of his professional friends, who have been present at his operations, have satisfied themselves that the muscle was in this state.

In such cases the muscle was not merely increased in bulk, but was also much more vascular, and of a deeper colour, than natural—conditions which contrast remarkably with the appearance the muscles of the eye present in their healthy state (*loc. cit.*, p. 28.) Dr. Franz also, in his answer to " Solomon Single-Eye," states that, in his experience, the muscles are frequently hypertrophied.

The common termination of the condition of a muscle, therefore, under preternatural excitement, is hypertrophy, whilst its fellow or antagonist becomes elongated, enfeebled, and atrophied. Mr. Middlemore confirms this statement also : he says, " one of the muscles of the eye-ball may become atrophic from an undue strength or action

of its antagonizing muscle, which, by controlling its power, limits its sphere of action, and induces wasting of its volume." (Vol. ii. p. 573.)

In the operation, when all the tendinous fibres and condensed cellular tissue are completely divided, the squinting eye usually regains its proper position, but in some few cases it is turned more than is proper in the contrary direction. How is it that this does not always take place? And how can we explain the fact of the eye only acquiring its healthy direction? Mr. Duffin, in a paper for the 19th of September, says that the most simple and natural reply to this query seems to be the fact that, in a state of health, voluntary muscles have no disposition to contract, unless called into action by an effort of the will; and that when the eye is restored to the position it ought to occupy, the abductor muscle, being then completely relaxed, will not draw it unduly outwards, unless that effort of the will be exerted. But to this I would remark that such results are not seen in nature; for how is it that strabismus occurs when the opposite muscle is weakened? how is the mouth, &c. turned towards the opposite side from paralysis of the muscles of the face? and, indeed, I might go on proposing numerous questions of a similar tendency. The fact is this: that all muscles, during their healthy state, although not in a condition of active contraction, maintain a degree of vital tonicity; antagonizing muscles act and react on each other. Instance the abdominal muscles, which always maintain a degree of uniform pressure on the contents of the abdomen, so that under all conditions this *cavity*, as it is called, is always *full*; the two surfaces of the peritoneum, when not separated by diseased action, are always directly in contact. My explanation is this: that in all cases where the muscle—the antagonist to the squinting side—is considerably elongated, in proportion to its bulk, its fullest contraction serves only to restore the eye to its proper direction; whilst, on the contrary, if this be not the case, the eye is turned outwards, remaining so until the reunion of the divided muscle restores the equilibrium of action. That this is true I think that I can prove, when we consider that even healthy muscles possess but a limited sphere of action, and that

if we relax a muscle beyond a certain degree, its fullest contraction will not serve to exert any power on its fixed points. This is beautifully illustrated by the following experiment, which should always be kept in mind in the treatment of dislocated thumb. If we forcibly bend the hand on the forearm, to its utmost degree, we so far relax the flexor pollicis longus as to render void the greatest voluntary effort to flex the last joint of the thumb; in fact we find that we have not the slightest power over it. From hence we learn that the fullest contraction of this muscle serves only to shorten it to a certain extent, and that if we exceed this degree its utmost efforts will exert no force whatever on its fixed attachments.

As a general rule, the tendency still to hold the same relative situation to each other is manifested in the eyes, even under these circumstances; and when one is, from the causes already mentioned, turned outwards, the other eye is turned inwards in a similar degree. But there appear to be exceptions in this case, in which it would be advisable to ascertain the duration, extent, and peculiarities. For an account and explanation of these cases I must refer to Mr. Duffin's paper of the 25th of September; premising, however, that I never saw or heard of any other cases of double divergent strabismus but those alluded to in that paper.

We may infer, finally, that the explanation of those cases, where the natural axis of vision only is restored by the operation, is, that elongation and debility of the muscle prevent further contraction; not that, in a state of health, voluntary muscles have no disposition to contract unless called into action by an effort of the will.

October 7th, 1840.

ON SOME PROPERTIES OF A COMBINATION OF ALBUMEN WITH ACIDS.

To the Editor of the Medical Gazette.

SIR,

I SHALL be glad if you think the accompanying observations worth recording.

I am, sir,

Your obedient servant,

H. BENCE JONES,
M.A., Trin. Coll. Cambridge,
Student at St. George's Hospital.

November 4th, 1840.

Dr. Burrows, in his lectures published in the 14th. vol. of the MED. GAZETTE, shewed that alkalies and their carbonates prevented the coagulation of albumen by heat ; and he pointed out the false deduction that thence might arise in cases of dropsy with albuminous and alkaline urine. It has happened to me to find that a similar error may occur in cases of albuminous urine in which a free acid is present.

The urine of a patient in St. George's Hospital was highly acid, gave a precipitate with nitric acid, which was not redissolved when heated. This urine would not coagulate with heat alone. I thence concluded that the precipitate with nitric acid was not albumen; nor was it until many months afterwards that I found that acid urine might contain albumen, and yet not coagulate with heat.

It has long been known that acetic acid prevented coagulation. Dr. Prout, in Thomson's Annals of Physiology, appears hereby to have distinguished incipient or chylous from serous albumen. He says, " on the addition of acetic acid and boiling, the fluid (chyle) coagulated ; this, therefore, was not albumen ;" and on adding acetic acid to acid urine containing albumen, or to dilute serum, and heating them, no coagulation will take place. Whilst making some experiments on this subject, I tried hydrochloric acid, and then I also found that if a minute quantity be added to urine, or dilute serum, that no coagulation with heat occurs : nitric acid I also found prevented coagulation. If to about a drachm of albuminous urine, or dilute serum, a drop of strong nitric acid be added, a precipitate will be formed which, on agitation, will be found to redissolve, and on heating this no coagulation will take place. I have even found, when trying to coagulate albuminous urine by heat in a test-tube which I had previously used in testing with nitric acid, and which I had not carefully washed, that the small quantity of acid left would prevent the formation of a coagulum even at a boiling temperature.

I have said that the precipitate first formed with a drop of nitric acid is redissolved. I attributed this, at first, to an excess of albumen ; but, by using

a much stronger solution of albumen, this precipitate was not more readily redissolved. The real explanation I have lately met with in Berzelius's Lehrbuch der Chemie, in which he says that the nitrate of albumen is soluble in water, but insoluble in dilute nitric acid. Hence the nitric acid should be added in excess, to precipitate the albumen permanently ; and it is therefore advisable in testing, to use a little albuminous urine, and put an excess of acid, instead of nearly filling the glass or test tube, and then adding only a drop or two of nitric acid.

There is apparently an error in what I have stated in cases where the urine or other fluid is alkaline, or rather where all the albumen is combined with alkali ; when, as Dr. Burrows showed, acid must be added before coagulation by heat can take place.

A boy was admitted into St. George's Hospital, May 1840, with anasarca and coagulable urine ; on the 13th he was bled. The serum was alkaline, milky, opalescent ; specific gravity 1·0158. Urine passed about the same time, after standing twelve hours, slightly alkaline; specific gravity 1·0142. Portions of urine and serum were heated separately ; both coagulated very slightly, becoming only cloudy, and giving no distinct precipitate : a small quantity of acetic acid being added to each, and both again heated, the serum gelatinized, while a heavy, curdy precipitate, took place in the urine. By excess of acetic acid both were prevented coagulating by heat. Dilute nitric acid (with care not to add too much or too little) exhibited the same phenomena. Here the albumen appeared to be first combined with alkali, and to be set free by a little acid when coagulation took place. By the addition of a little more acid in the one case, and acetate in the other, a nitrate of albumen was formed, both which are soluble in water. If too much nitric acid was added, the nitrate of albumen became insoluble in the dilute nitric acid then present.

A diagram may perhaps make this more clear.

The serum in the blood consisted of albuminate of soda, water, &c. to which acetic acid being added, we have

Albumen ——————Set free ; coagulable by heat.
Soda . . . ~
Acetic acid _____ Acetate of soda, soluble.

U

If more acetic acid was added than was sufficient merely to combine with the soda, we have

Albumen ————————→ Acetate of albumen soluble in water, and uncoagulable by heat.
Soda . . .
Acetic acid
Acetic acid ————————→ Acetate of soda, soluble.

In the urine the albumen was probably combined with ammonia, forming an albuminate of ammonia, which Dr. Burrows found uncoagulable by heat ; to this, if a small quantity of nitric acid be added, we have

Albumen ———————— Set free ; coagulable by heat.
Ammonia
Nitric acid ———————→ Nitrate of ammonia, soluble.

If a little more nitric acid was added than was sufficient to combine with the ammonia, we have

Albumen ————————→ Nitrate of albumen soluble in water, and uncoagulable by heat.
Ammonia
Nitric acid
Nitric acid ————————→ Nitrate of ammonia, soluble.

If more nitric acid was added than was sufficient to form the nitrates of albumen and of ammonia, dilute nitric acid became also present, in which the nitrate of albumen is insoluble, although it is quite soluble in water.

From the above we may infer that the quantity of albumen present in urine cannot be estimated to the degree of coagulation by heat.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Animal and Vegetable Physiology considered with reference to Natural Theology. By P. M. ROGET, Sec. R.S., &c. &c. Third edition, with numerous additions and emendations.

THIS, one of the best of the Bridgewater Treatises, has already reached the third edition—a proof of its excellence, and of the estimation in which it is held by the scientific world.

It is stated in the preface that " the object of this treatise is to enforce the great truths of Natural Theology, by adducing those evidences of the power, wisdom, and goodness of God, which are manifested in the living creation." The author has accordingly confined himself to such facts as afford evidences of design, and these facts he has arranged in a scientific form. " By furnishing those general principles, on which all accurate and extensive knowledge must substantially be founded, this compendium forms a useful introduction to the study of Natural History, the pursuit of which will be found not only to supply inexhaustible sources of

intellectual gratification, but also to furnish, to contemplative minds, a rich fountain of religious instruction." To render these benefits generally accessible, Dr. Roget has treated such subjects only as are adapted to every class of readers of either sex.

By comparing this with the two former editions, it will be found to contain a great number of valuable additions ; indeed, the science of physiology is so extensive, and so many eminent individuals have recently devoted themselves to its cultivation, that it was incumbent on our author to give a summary of all that had been previously done in this most interesting branch of knowledge, so as to be adapted in every respect to the present advanced state of the science. Many parts, especially of the chapters on the circulation and on the nervous system, have been recomposed. A summary has been given of the recent researches and theories of Schleiden and of Schwann on vegetable and animal development—of Breschet's discoveries respecting the structure of the skin—of the very general presence of cilia, and of their mode of action—of fossil infusoria— of the most recent inquiries regarding the infusoria — Mr. Moseley's theory of discoid shells - the mode of formation of the epiphragma of the helix, &c. These are a few of the more interesting additions with which the present volumes abound. The recent microscopical discoveries on the structure of ivory, and the new views relating to dental development, have, we observe, not been passed unnoticed. In short, we regard these volumes as valuable, not merely to the general reader, to all classes of whom

they are admirably adapted, but as conveying to the more profound physiologist a very comprehensive and accurate summary of the present state of physiological knowledge. The simplicity of style, and clearness of expression, are such as cannot fail to engage the attention of those who are entering on the study of physiology. Indeed, we recommend these volumes with great confidence to the notice of all classes of readers, as containing much valuable information of the most interesting kind.

MEDICAL GAZETTE.

Friday, November 13, 1840.

MORTALITY IN ENGLAND AND WALES.

MR. FARR observes, in the letter to the Registrar-General, on which we commented last week, that while the mortality of men is 7 per cent. higher than that of females, the liability of the two sexes to death from particular diseases is very various. Thus, in 1838, hooping-cough carried off 4036 males, and 5071 females; and consumption destroyed 27,955 males, and 31,090 females; while, on the other hand, 4242 males, and only 3430 females, died of hydrocephalus; and 152 males, and only 55 females, of diabetes. Mr. Farr attributes the excess of mortality from consumption among women to their in-door life, and the use of stays; but we should have supposed, theoretically, that these causes would have been counterbalanced in the other sex by their intemperance and extreme exposure to inclement weather—causes which must certainly excite phthisis in the predisposed. We are inclined to attribute more to the compression of the thorax than to confinement within doors; but much, no doubt, also arises

from an original difference of temperament. According to the registers, 2032 males, and 1530 females, died of diseases of the heart and blood-vessels; but Mr. Farr remarks, that this is below the true number; for though the diagnosis of these maladies has been considerably improved, the art of auscultation is not generally diffused. "1338 males, and 313 females, died of diseases of the urinary organs. The mortality of the former from the stone and gravel was 4 in 100,000; of the latter, 0·5. The difference in the 7 heads is exaggerated by, but it cannot be exclusively attributed to, mechanical causes." (Mr. Farr, p. 73.) Thus, the mortality from stone and gravel was eight times as great among men as among women; a disproportion, which, though great, is less than one might have imagined.

The deaths in childbirth and from miscarriage were about 5 in 1000 cases, while in the previous year, 1837, they were only 4 in 1000.

The deaths of 125 males and 36 females are attributed to intemperance. This head does not include those who died of *delirium tremens*, nor the mass of diseases which are caused by excess, but seems to be limited to some of the instances where the excess was so gross, as to have become notorious among the neighbours of its victims.

As the chief instruments of intemperance are beer, wine, spirits, and opium, Mr. Farr gives the increase which has taken place of late years in the consumption of each. "The decennial rates of increase were for malt, 24; wine, 27; spirits, 39; opium, 53 per cent." The quantity of wine consumed in this kingdom was, and is, so curiously small, as mathematically to demonstrate the oppressiveness of the duty levied on it; and to show with equal clearness how difficult it is for gentlemen of £5000 a year to sympathize with the

domestic arrangements of those on whom fortune has looked more coldly. The quantity of spirits used is certainly too great ; but the best check on this will be the reduction of light wines to one-half or one-third of their present price; and we trust that the war mania of the French may not deprive us of this reciprocal advantage. The opium entered for home consumption from 1820-4 was 19,276 lbs. annually; but from 1834-8 it was 33,482 lbs. annually —a painful increase !

The deaths ascribed to starvation in 1837 were 64 in number ; in 1838 they were 123, exclusive of infants under one year old. Some of these were from cold, others from hunger, many from both united. It appeared from some correspondence in the newspapers a few months ago, that the Poor Law Commissioners do not like these investigations of Mr. Farr into cases of death from destitution. In respectable Malthusian society you must not mention such words as " cold," hunger," " want of the necessaries of life." They would think you a philanthropist, or what not; and we should recommend the prudent to be eminently cautious in such company. Addison tells a story of a knot of country people, who having got hold of a copy of " The Whole Duty of Man," were persuaded that it was a satire especially written against their village; and we warn those whom it may concern that if they utter such inflammatory words as " starvation," "misery," "neglect of the poor," or the like, the Commissioners may put in force the powers with which they are entrusted against those who obstruct the working of the Act. On the other hand, a convenient doctrine, to be secretly rather than openly lauded at Somerset House, has been broached in the Kensington Union. It is, that to shelter the houseless is a crime punishable by imprison-

ment. Only let this be universally established, and the foul ulcer, pauperism, must be excised. "To say to the poor, ye shall eat the bread of affliction, and drink the water of affliction, and be very miserable while here, required not so much a stretch of heroic faculty in any sense, as due toughness of bowels. If paupers are made miserable, paupers will needs decline in multitude. It is a secret known to all rat-catchers ; stop up the granary crevices, afflict with continual mewing, alarm, and going-off of traps, your ' chargeable labourers' disappear, and cease from the establishment. • • • Rats and paupers can be abolished ; the human faculty was from of old adequate to grind them down, slowly or at once, and needed no ghost or reform ministry to teach it."*

" I am not only witty myself," says Falstaff, " but the cause of wit in others ;" and your zealous starvationist, not satisfied with " carrying out the Act," as the phrase is, to its full extent, likes the same refusal of succour in all quarters ; he pines to see the " due toughness of bowels" epidemic ; and wishes sympathy to be treated like a vagrant, as it is.

These reflections have been suggested by the report of an inquest which was held at Kensington on the 27th of October, and the 2d of the present month, before Mr. Wakley, on the body of Elizabeth Friry. It is difficult to give, in a moderate compass, even the main facts of a case which occupies more than three columns in the Times of November 4th; but the following seems to be its gist. The deceased, who was labouring under extreme indigence and sickness, superadded to the weight of sixty-five years, lodged at the house of a poor woman named

* Carlyle's Chartism, p. 17.

Ryan, at 4, Pembroke Place, Kensington, where she had nothing but the boards to lie upon. The day before her death she was seen by Mr. Wright, a Union surgeon ; and Ryan says she asked him " if he would be so kind as to give me an order to get the deceased into the workhouse; to which he replied, he knew nothing about it, as he was afraid Mr. Madden would give me imprisonment for keeping such a person in my house, if I went to him." Very soothing, truly, to the dying woman, who " heard Mr. Wright speak about imprisonment." Soon afterwards, Mr. Madden, the relieving officer, visited the house, and, when he left it, Ryan " ran down after him into the road, and told him what Mr. Wright had said about imprisonment, when Mr. Madden said a prison was good enough for me, as I had no business to keep such a person as the deceased in the house." This story of the threat is not, as might be supposed, an extravagant fiction of the witness Ryan ; for Mr. Wright says in his evidence, " I certainly did tell Ryan she might get into trouble, and might probably be sent to prison for harbouring deceased.   I have often told persons so before, and may again." The end of the case was, that, on the Monday, about 12, a cart was procured to convey Elizabeth Friry to the workhouse, but she had been dead some minutes.   Mr. Madden, who is registrar of deaths, as well as relieving officer, entered it as a case of dropsy, from Mr. Wright's information ; but, unfavourable rumours having been bruited, Mr. Wakley very properly issued his warrant for the disinterment of the body. The post-mortem examination was performed by Mr. Wildbore, of Fleet Street. There was a deposit of lymph on the posterior part of the cerebrum, and both the dura and pia mater were vascular ; but the point which struck him most was the unparalleled emaciation of the

corpse ; it " was little more than bone and integument all over."

The verdict of the jury was, " We find that Elizabeth Friry died from fever, brought on by the want of good and sufficient nourishment ; and that the jury cannot separate without expressing their disapprobation of the conduct of the relieving officer and of the surgeon in not being more prompt in their attention to the wants of the deceased ; and, at the same time, the jurors think it right to express their condemnation of a system which allows the offices of relieving officer and registrar of deaths to be united in and held by the same person."

Messrs. Wright and Madden do not appear to have committed any legal offence ; and poor Friry had been so long worn down by the fiercest extremities of want, that it is unlikely that the most sedulous kindness could have resuscitated her.   But it is too clear that her unwillingness to apply for relief had been produced by the harshness with which such applications are now treated ; and it is equally obvious that the officers of the Kensington Union understand their mission but too well. *Lower the rates* is the cry of the economists, and nothing can be easier, if the due misanthropy be not wanting.   The poor can be ground down, as Thomas Carlyle has it, slowly or at once.   Here is unquestionably another case for Mr. Farr's gloomy list.

The number of violent deaths is greater than we could have supposed. They amounted to 11,727 persons, of whom 8357 were males, and 3368 females. More than a thousand of these were suicides.   The tendency to suicide is greatest in London, and least in Wales.   This is just as it might have been presupposed.   The pulses of life beat most equably in a secluded province, and most feverishly in the capital of the world ; it is like the difference between playing for six-

pences, and staking your fortune on each throw !

The excessive mortality of dense populations is a well-established fact. Mr. Farr is perhaps too sanguine in hoping that this is not inevitable ; and he observes that in London itself there is the greatest variety in the healthiness of districts ; so that the mean duration of life is from 25 to 30 years in the eastern, and from 40 to 50 in the northern and western districts.

The improvements which he suggests are all desirable and all practicable. Better drainage, and the disuse of burial in towns, are among them; to which we would add some forcible restraint on the cupidity of those landlords who build houses in such a style that they are necessarily foci of disease. Among the more remarkable deaths we observe three from taking Godfrey's cordial, one from the application of calomel to cure the itch, and one from sea-sickness.

We now take leave of Mr. Farr, giving him our hearty thanks for his efforts to diffuse information on so important a subject.

SIR ANTHONY CARLISLE.

WE have this week to record the death of Sir Anthony Carlisle, which took place on the 2d inst., in the 73d year of his age The deceased was born near Durham, in 1768, and commenced his professional studies under the auspices of an uncle who practised at York. At an early age he was sent to London, and studied under Hunter, Cruikshank, and Baillie. In 1793 he succeeded to Mr. Watson at Westminster Hospital. He delivered a regular course of lectures on surgery for many years, and contributed largely to the Philosophical Transactions and other scientific works ; indeed, his name is to be found more frequently in the medical and other periodicals, since the early part of the present century, than that of almost any other writer. His love of publishing did not entirely abandon him to the last. In this journal for March 8th, 1828, will be found a paper on Erysi-

pelas from his prolific pen, and more recently he has frequently figured in the newspapers. He was also the author of several Croonian lectures, and Hunterian orations, as well as of a separate work on the " Disorders of Old Age and Means of prolonging Human Life." He was knighted by George the Fourth when Prince Regent; he was for many years a member of the Council of the College of Surgeons, and one of the Board of Examiners; and twice filled the office of President. He was one of the curators of the Hunterian Museum, and Professor of Anatomy to the Royal Academy, an appointment which he held for sixteen years.

It will thus be seen that Sir Anthony led rather a bustling active kind of life. He had the character, moreover, of being rather bigotted and tenacious—in the College of Surgeons obstinately supporting the old doctrines of a by-gone age, and persisting in retaining his situation of surgeon to Westminster Hospital when all who wished him well must have been anxious for his retirement. There is a portrait of him by Shee, which represents the Knight as a well-dressed and rather gentleman-like person. Of this we can only say, that if it ever resembled him he had changed marvellously before the period of our first seeing him.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.
November 10th, 1840.
DR. CLENDENNING IN THE CHAIR.

THE first meeting of the present Session was held at the Society's Rooms on Tuesday evening last. The room was from the commencement well filled by the members of the Society, and the friends introduced by them. In consequence of the unavoidable absence of the President, Sir B. C. Brodie, the chair was taken by Dr. Clendinning, one of the vice-presidents, and for the same reason, we presume, the business of the society was at once commenced without the usual speech, or any other special formality. After the reading of an abstract of the proceedings of the last meeting of the last session, and of a list of the numerous works presented to the Library of the Society during the vacation, a paper was read on the Mode of Observation to be adopted in the Investigation of the Diseases of the Nervous System, by Dr. Marshall Hall, of which an abstract will be given next week.

At the conclusion of the paper an animated

discussion took place between Drs. Burne, James Johnson, Weatherhead, Addison, Marshall Hall, and others, which continued till the usual period for the adjournment of the meetings had arrived.

On the table there were two specimens of fracture of the neck of the femur within the capsule, in both of which there was bony union. A description of one of these, by Mr. Stanley, was intended to have been read, but the discussion on Dr. M. Hall's paper having occupied all the Society's time, the reading of the former was postponed to the next meeting.

<hr>

BREVIATE

OF THE

DRAFT OF THE MEDICAL BILL,

BY MR. HAWES.

CLAUSE 1. Preamble.

2. Interpretation clause : " Art of Medicine "—" Medical Practitioner " — " Chemist and Druggist."

Clauses referring to Registrar.

3. Secretary of State to appoint three Registrars—one for each kingdom. Lords of Treasury to fix salaries and expenses necessary in carrying Act into Execution until the election of first Councils (*for appointment of future Registrars, etc. see clauses 12 and 13.*)

4. Registrars to grant certificates to practise the Art of Medicine to all persons at present legally entitled to practise Medicine or Surgery in any part of the Kingdom — Registrars to grant them for the part of the Kingdom only for which they are appointed to act.

Medical Lists.

5. Annual payment for certificate, which is to be renewed annually, and a list of the persons obtaining a certificate to be published every year by the respective Registrars—the persons whose names appear in such lists alone to have a vote for the respective Councils.

Councils.

6. A Council to be elected in each Kingdom every three years—twenty Councillors for each.

7. Candidates for office of Councillor to be nominated by any six persons entitled to vote sending a notice to the Registrar forty days previous to election—the names of persons nominated to be printed in voting papers, together with the names of the persons nominating.

8. Election to be held within four miles of General Post Office, London, and within two miles of the General Post Offices in Edinburgh and Dublin.

9. Voting to be by ballot—voting paper either delivered personally, or sent by post, enclosed in a declaration of vote direct to Registrar—Registrar to send a voting paper and declaration to every Medical Practitioner fourteen days before election.

10. The twenty persons having a majority of votes to be elected—Registrar to add up votes—if there be any equality of votes, to ballot publicly out of the persons having the equal votes so many as may be required to make up the twenty—after first election, Councils to appoint two persons to superintend the election—at the first, Secretary of State to appoint two.

11. The Universities of Oxford, Cambridge, and London, the College of Physicians and of Surgeons and Apothecaries' Company, London — the Universities of Edinburgh, Glasgow, St. Andrew's, and Aberdeen, and the College of Physicians and of Surgeons, Edinburgh, and the Faculty of Physicians, Glagow—Trinity College, Dublin, and the College of Physicians, and of Surgeons, and the Apothecaries' Society, Dublin—each to send one member to their respective Councils.

12. Registrars after the first election of Councils to be appointed by the respective Councils.

13. Councils may remove their Registrar —to give notice of the vacancy—President of Council may appoint deputy, in case of temporary disability of Registrar.

14. Each Council to elect a President—appoint a Treasurer—three Auditors of Accounts—Clerks — to fix all salaries — to fix remuneration to each Member of Council for every attendance.

15. Questions to be decided by majority, one half of the whole Council being present—Meetings to be summoned three days.

16. Special Meetings may be called by President or three Members of Council—every summons to specify business to be transacted.

17. All monies and fees to be paid to Treasurer—out of which all expenses are to be paid, and the surplus may be spent in the advancement of Medicine and Literature, &c.

18. Treasurer to pay money only upon an order, signed by three Councillors and the Registrar.

19. Accounts to be audited twice a year, and to be published in the respective medical lists.

20. Councils may sue and be sued in the name of their Registrar.

Senate.

21. Councils each to select three persons every five years to form a Medical Senate.

22. Registrar of England to be Registrar of Senate.

23. Senate to meet in London once every year — expenses of members to be paid by the respective Councils—special meeting may be called, or place of meeting may be altered by any two Councils or Secretary of State, fourteen days' notice of such meeting to be given to the Members of Senate—Senate may, when once met, adjourn from time to time until dissolved.

24. All questions coming before the Senate to be negatived, unless a majority of the whole Members of Senate assent thereto.

25. To appoint a President.

26. Members of Senate may attend any meeting of any Council or any examinations.

27. Expenses of Senate to be paid in equal portions by the three Councils.

28. Senate to make bye-laws to regulate education of Students, and the examinations for Diploma of Qualification to practise Medicine or to carry on trade of Chemist and Druggist—bye-laws to be published in *London Gazette*—may be disallowed by the Queen in Council—if first Senate neglect to make bye-laws within twelve months, Secretary of State to do so.

29. To publish a Pharmacopœia.

Disqualification.

30. No person to practise the Art of Medicine after February 1, 1842, unless he possess a certificate (*see clauses* 4, 32, *and* 34), or carry on the trade of Chemist and Druggist after December 1, 1842, without a license (*see clause* 35).

31. No bodies after bye-laws are published to grant a Diploma, certificate, or license to practise the Art of Medicine, except according to this Act.

Qualification.

32. Council to appoint examiners annually—to examine subject to the rules laid down by the Senate—Council to order Diploma to be granted to persons upon the recommendation of examiners—persons obtaining Diploma of qualification to practise Medicine, to be entitled to obtain a certificate for any part of the Kingdom, in the same manner as persons entitled to them at time of passing this Act—Persons obtaining Diploma of Qualification as Chemist and Druggist, to be entitled to license.

33. Medical men entering Army or Navy to possess a Diploma.

34. Persons practising as Dentists or Cuppers at the time of the passing of Act, to have certificate to continue to practise as Dentist or Cupper.

Chemists and Druggists.

35. Registrars to grant licenses to persons obtaining Diploma of qualification to carry on Trade of Chemists and Druggists upon a payment annually—licenses to be renewed—a list of persons obtaining a license to be published in medical lists—all persons at present being Chemists and Druggists or assistants, or apprentices, claiming the exemption within twelve months, to obtain licenses, and not to be called upon to renew them annually, unless they desire—if they renew them, their names are to be published in the respective medical lists, and not otherwise.

Assistants and Apprentices.

36. Medical Practitioners and Chemists and Druggists to make declaration of assistants and apprentices in their employ annually — persons being assistants must possess a certificate or license, unless they be apprentices—Assistants not to renew their certificate or license annually.

Medical Practitioners.

37. Powers and privileges of Physicians, Surgeons, and Apothecaries, to be transferred to Medical Practitioners under this Act.

38. May recover charges for professional visits and consultations.

39. Medical Practitioners and Chemists and Druggists to be exempt from serving on juries and other offices.

Penalties.

40. On Registrar, or his deputy, for wilfully neglecting or refusing to discharge duties imposed upon them by this Act.

41. For illegally obtaining or attempting to obtain a Diploma, certificate, or license.

42. For making a false declaration.

43. For practising Medicine without a certificate, or trading as a Chemist and Druggist without a license.

44. For employing or acting as an assistant without being qualified, or for neglecting to make a declaration of assistants and apprentices.

45. Penalties to be recovered before one magistrate in London, or two elsewhere.

46. If penalty not paid, magistrate to commit to prison—one half of pecuniary penalties recovered to go to informer, the remainder to the Treasurer of the Council where offence committed.

47. Persons convicted may appeal to Quarter Sessions.

48. If any day fall on Sunday, business to be transacted on the following day.

49. Act may be amended during Session.

UNIVERSITY OF LONDON.
Bachelorship in Medicine.

SECOND EXAMINATION. — PASS EXAMINA-
TION.—1840.

Monday, November 2.—Morning 10 to 1.
Examiner, Dr. ROGET.

1. What are the peculiarities in the cir-
culation through the Liver; what pur-
poses in the economy are served by that
organ; and what are the structures which
perform similar offices in invertebrate
animals?

2. Specify the principal anatomical
differences between the structure of Man
and that of the Quadrumana.

3. Explain why the lungs collapse, on
an opening being made in the parietes of
the thorax.

4. Describe the conditions of the eye
producing Myopic and Presbyopic vision;
state the optical causes of the indistinct-
ness of vision under these conditions; and
explain the optical principles on which
these defects may be artificially remedied.

5. Explain, on mechanical principles,
the advantages derived from the tubular
form of cylindrical bones.

6. Describe the mechanism of respira-
tion in Fishes; and assign the reason of
their dying when placed in atmospheric
air.

7. What purposes are answered by the
Eustachian tube; and why is deafness
consequent on its obstruction?

8. Describe the progressive changes
which occur in the organs of circulation of
the Frog, during its transition from the
Tadpole to the adult state.

9. Describe the peculiarities of struc-
ture in the skull and bones of the face of
the carnivorous family of Mammalia, as
contrasted with those of Herbivorous
tribes.

Afternoon, 3 to 6.
CELSUS DE RE MEDICA.

Examiners, Dr. BILLING and Dr. WATSON.

Various quotations from different Books
of Celsus.

Tuesday, November 3.—Morning, 10 to 1.
SURGERY.

Examiners, Mr. BACOT & Sir S. HAMMICK.

1. Give the classification of Wounds
arising from external violence; their na-
ture, symptoms, and treatment.

2. Describe the symptoms and treat-
ment of both idiopathic and symptomatic
Erysipelas; and state in what cases, and
under what circumstances of external in-
jury, Erysipelas most commonly occurs.

3. Detail the symptoms of a strangu-
lated Inguinal Hernia—the methods you
would employ for its reduction, and if

they were unsuccessful, at what period and
under what circumstances would you pro-
ceed to the operation;—describe the mode
of operating, and give the subsequent ma-
nagement of the patient, according to the
various conditions of the contents of the
Hernial Sac.

4. Enumerate the different dislocations
of the Hip Joint; the mode of detection,
and the manner of reduction of each re-
spectively.

4. For what Injuries or Diseases would
you amputate at the Shoulder Joint?
Describe the operation and after-treat-
ment.

Afternoon, 3 to 6.
MEDICINE.

Examiners, Dr. BILLING and Dr. WATSON.

1. How do we judge of the propriety—
and of the requisite amount—of Blood-
letting, in inflammations?

2. What are the progressive symptoms,
morbid appearances, and treatment of
Pertussis? State particularly the symp-
toms which would indicate the necessity
for blood-letting.

3. State the usual causes of Diarrhœa,
how it is to be distinguished from dysen-
tery, and the treatment under different
circumstances.

4. Describe the symptoms and usual
course of measles, the varieties of the dis-
ease, the chief sources of danger, and the
treatment.

5. What parts are most commonly the
seat of Neuralgia? give an outline of the
treatment.

6. Describe the symptoms, and ordinary
course and treatment of *Erysipelas of the
Head and Face.*

7. What are the signs of *Delirium Tre-
mens?* How is it distinguishable from
Phrenitis? Lay down the methods of cure
respectively suitable to these two diseases.

8. *Emphysema of the Lungs.*—State fully,

   (1.) Its anatomical characters.

   (2.) Its effects (when extensive), in
modifying the shape of the Thorax.

   (3.) Its auscultatory signs.

   (4.) Its general symptoms.

   (5.) The means by which these may
best be relieved.

9. Describe

   (1.) The symptoms which denote
that a calculus is descending from the
kidney towards the bladder.

   (2.) The symptoms which warrant
the belief that the calculus has re-
cently entered the bladder.

   (3.) The indications of treatment
in either case, and the means of ful-
filling them.

10. What are the symptoms, anatomical
characters, and proper treatment of *Peri-
tonitis?*

Wednesday, November 4.—Morning, 10 to 1.

MIDWIFERY.

Examiner, Dr. LOCOCK.

1. The anatomical relations between the mother and the fœtus, in the Human subject.

2. The changes which take place in the Human Ovaries from impregnation and during menstruation.

3. The causes of protracted Labour.

4. The varieties of Puerperal Convulsions, and their several treatment.

5. The pathology of Phlegmasia dolens.

6. The symptoms and treatment of Exhaustion from hæmorrhage.

7. The immediate and remote causes of Infantile Convulsions.

Afternoon, 3 to 6.

FORENSIC MEDICINE.

Examiners, Prof. DANIELL, Dr. LOCOCK, and Mr. PEREIRA.

1. How would you distinguish, in the case of a person found hung, whether the suspension was before or after death ?

2. By what symptoms would you distinguish a case of poisoning by Opium from one of Apoplexy ?

3. In what cases of poisoning is artificial respiration a remedial agent ; and what is the simplest and easiest method of effecting it ?

4. What are the impediments to the action and the fallacies of Marsh's test for arsenious acid ; and how would you obviate them ?

5. What are the substances used as hair dyes ; and how would you distinguish stained from natural hair ?

6. The causes of Sterility—which remediable, and which not.

7. The most frequent causes of death from *Malpraxis* during the act of parturition—and the distinction between natural appearances and the effects of violence as discovered after death.

8. The diagnosis of Mania—Melancholia—Monomania—Dementia—and Idiotism.

VACCINATION CONTRACT.

To the Editor of the Medical Gazette.

SIR,

I TRUST the importance of the following subject to the medical profession and the public will obtain for it a place in the next number of your valuable journal.—I am, sir,
            Yours very respectfully,
                    GEORGE DRUMMOND.

Croydon, Nov. 4, 1840.

In accordance with the instructions of the Poor Law Commissioners, the Guardians of the respective Unions have issued, or will issue, circulars to some or all of the medical practitioners in such Unions, offering to contract with them to vaccinate all persons who may apply to them, on terms very inadequate to the importance of the duty imposed. Such circulars have been variously received in different Unions. In some Unions persons have been found imprudent or mean enough at once to accept the proffered insult : in some the contemptible offer has been rejected with disdain. Some practitioners have demanded a larger remuneration, while others have considered the extension of the contract to others than paupers a work of supererogation, and have treated it with silent contempt. As practitioners have almost universally vaccinated the poor gratuitously, the general dislike of the profession to the contract arises less from the amount of remuneration offered for the vaccination of the poor, than from the extension of the contract to all classes in society ; thereby depriving the contractor of his honest right to claim from the more opulent a just reward for his services. The latter objection to the contract has been entirely removed to the satisfaction of the medical practitioners in the Croydon Union, by alterations in the contract, which alterations have been sanctioned by the Commissioners.

The most important alteration consists in declaring the remuneration to be for *reporting only*, leaving unaltered the right of the profession to claim from their patients the usual fee for the operation ; thus making the allowance by the Guardians an addition to, rather than a substitution for, their former remuneration, and requiring for such addition reports to be made.

Should such a system be generally adopted, the medical profession will, I trust, co-operate with the Commissioners in bringing to maturity that national blessing, which (to the honour of the profession be it said) they have given birth—the extermination, or, at any rate, the mitigation of a loathsome disease, attended annually in England and Wales alone by a sacrifice of 12,000 lives, and by the suffering of 36,000 from its effects.

The same concession made by the Commissioners to the Croydon Union, will, I have no doubt, be extended to other Unions, if the practitioners in the respective Unions in a body claim it. To give at length my correspondence with the Guardians would encroach too much on the pages of this journal. I therefore briefly state that (the Guardians having requested me to make such alterations in the contract as would remove the objections of which I had complained,) I sent them an altered contract, of which the following is an abstract :—

It is hereby agreed, and the said
doth contract with the said   that
from and after the   day of
he will vaccinate all persons who shall apply
to him, at any reasonable hour of the day, at
his own residence, and do and perform all
other acts and things, as shall be necessary
for the immediate purpose of causing such
vaccination to be successfully terminated.
And that he will keep books, give certificates,
and report small-pox cases. And for the
above-described reporting, the said Guardians
agree to pay to the said   the sum
of   for every case of vaccination,
which shall have terminated successfully,
having been conducted and reported by the
said   according to the terms of
this contract. And it is hereby further
agreed, that (as the above remuneration by
the said Guardians is for reporting only), this
contract is not to be construed in anywise to
alter or interfere with the payment by those
who can afford it, of such fee for vaccination,
as was customary before this contract was
made.

Twenty-eight days' notice, by either party,
to put an end to the contract.

In witness whereof, &c. &c.

The Guardians having obtained the sanc-
tion of the Commissioners to the above con-
tract, have now adopted it; and although the
remuneration for reporting is only one
shilling and sixpence per case, most of the
medical practitioners in the Union have
accepted the appointment of vaccinators.

The letter from Mr. Nankivell, in the last
number of the Lancet reflects great credit on
the professional consistency of the medical
practitioners of St. Columb; and I respect-
fully submit that the adoption of the above
contract in that Union would accord with
the intentions of the guardians, and the con-
sistency of the practitioners.

DEATHS FROM SMALL-POX.

To the Editor of the Medical Gazette.

SIR,

I BEG to enclose the copy of a circular sent
to the registrars by the Registrar General.
If you should deem it proper to call the
attention of medical practitioners to the sub-
ject, and to request them to investigate the
points referred to, it could not fail to do
good. The medical man in attendance
would, of course, gain more accurate infor-
mation as to previous vaccination than a
common informant could give the registrar.

I am, sir,
Your obedient servant,
WILLIAM FARR.

Nov. 7th, 1840.

(CIRCULAR.)

General Register Office,
October 31st, 1840.
SIR,

IN consequence of the great number of cases
of death from small-pox in the metropolis, I
am directed by the Registrar General to
recommend that in every case of death from
small-pox registered by you, you shall
inquire whether the individual who has died
had previously had small-pox, or been vac-
cinated, or not—and if informed on that
point, shall insert in the column of your
register headed " Cause of Death," under
the words " small-pox," the following ad-
ditional words : " after natural small-pox,"
—" after small-pox by inoculation,"—" after
vaccination," or " without previous vac-
cination," as the case may be.—I am, sir,

Your obedient servant,
THOS. MANN,
Chief Clerk.

CORNWALL MEDICAL ASSO-
CIATION.

To the Editor of the Medical Gazette.

SIR,

I HAVE taken the liberty of enclosing to you
a printed copy of resolutions passed at the
first meeting of the Cornwall Medical Asso-
ciation. I shall feel obliged if you can get
them inserted in your valuable journal.

I am, sir,
Your obedient servant,
J. H. NANKIVELL, Sec. of C.M.A.

St. Columb, Nov. 5, 1840.

At a meeting of medical practitioners held
at the Red Lion Hotel, St. Columb, on
Monday, the 19th of October, 1840, J. Fry,
Esq. in the chair,

It was unanimously resolved—

1. That this meeting do constitute itself
into a society, to be called the " Cornwall
Medical Association," having for its object,
by the individual and united efforts of its
members, the maintenance of such princi-
ples of medical reform as shall conduce to
the welfare of the public, and the general
benefit of the profession.

2. That the following are the principles of
medical reform which are approved of by
this Association : — viz. That all legally
qualified practitioners shall form a faculty of
medicine, who shall elect a senate for each
capital in the United Kingdom. That these
senates shall be subject to the same laws and
regulations, and shall form by-laws for the
government and protection of the faculty.
That the members of the existing medical
corporations shall be invited to take part in
the formation of the first senate. That all
candidates for degrees in medicine shall be

publicly examined by a board elected as the senate shall suggest. That a high medical qualification shall be demanded from candidates, who shall receive equal rights, titles, and privileges; and that a register shall be kept of the names of the members of the faculty; and that no one whose name does not appear on the register shall be entitled to practise. That no member shall sell drugs, or compound medicines, (unless prescribed by himself, or others in consultation with him, and for his own patients,) except by special license.

3. That committees shall be formed of the members of this Association, residing in the towns or parishes comprised in any Union; and that it shall be a by-law,—That no member of this Association will offer his services to any public institution, (under the Poor Law Act,) without previously taking the sense of the members of the committee as to the amount of remuneration to be required for such services. Also,—That the members of each committee shall meet, on the second Monday of every March, at the town or place in which the Poor Law Union is centred, for the purpose of submitting to each other the subject of any medical contract which may be proposed; and that no member of the profession who may allow himself to be introduced into any neighbourhood, by Poor Law Commissioners, or otherwise having the management of the poor, in opposition to any resolutions adopted by this society, in either of its divisions, shall be deemed eligible as a member of the Cornwall Medical Association; or countenanced in any way, professional or otherwise, by any member of this society.

4. That the members of this Association shall meet twice in each year for the general interest of the profession, viz. on the first Monday in every March, and on the first Monday in every September; the next meeting to be held at Bodmin. when and where the succeeding place of meeting will be fixed on.

5. That each member shall subscribe annually the sum of £1. for the purpose of defraying the necessary expenses of the society, and the foundation of a medical library: and that another object of the society shall be the discussion of medical and other scientific subjects, at the periodical meetings.

6. That at the next meeting a proposition shall be brought forward to consider the propriety of uniting this association with the " Provincial Medical and Surgical Association:" and also of establishing a benefit fund for the relief of widows and orphans of deceased surgeons, or members of the profession in cases of distress.

7. That a petition, embracing the princi-

ples of reform, as set forth in the second resolution, and as well humbly praying that parliament will take into consideration the propriety of establishing an equable and uniform system by which medical practitioners shall be remunerated as contractors with Poor-law Guardians, shall be prepared and signed by the members of the Association, (or the president on their behalf,) and that the county members be respectfully requested to present the same in the approaching session.

8. That a copy of the resolutions, passed at this meeting, shall be printed and forwarded to every member of the profession in the county, with the object of forming as extensive an Association as possible.

9. That Mr. Nankivell be appointed secretary, (pro tempore,) and Mr. Moorman, treasurer, (pro tempore,) and that the first subscriptions shall be paid into the hands of the treasurer, at the ensuing meeting at Bodmin.

MEDICAL CORONERS.

To the Editor of the Medical Gazette.

SIR,

MAY I direct your attention to a rather singular statement made in to-day's Times in reference to the accounts of the coroners for Middlesex. The magistrates reported that Mr. Wakley's charge "for attending 107 inquests amounted to £74. 8s. 6d., while Mr. Baker's charge for holding 88 inquests amounted to £121. 14s. 6d.; being an average, in the case of the former coroner, of 13s. 11d. per inquest, whilst in the latter it was £1. 10s. 5d." On an explanation of this difference being requested, it was stated that the heavier charges of Mr. Baker arose from the number of post-mortem examinations he had ordered. Not having former accounts before me I cannot say whether this discrepancy in the proceedings of the two functionaries in this instance is accidental or not. If not, and the greater frequency of post-mortems directed by Mr. Baker is the true explanation of the difference, I must say medical men have little cause to congratulate themselves for the trouble they took in securing the election of a medical candidate. Not that I would wish to see the interests of my profession preferred to those of the public at large (although this same public uses us strangely enough sometimes), but I believe that the true interests of the community, as certainly the progress of science, would be (seeing that we have no public officer properly educated and trained for the prosecution of inquiries in medical jurisprudence) most advanced by post-mortem examinations being instituted in every

case of sudden death, and indeed under all circumstances in which a coroner's interposition can be necessary. But it will be said that I am labouring under error, and that we here see one of the benefits resulting from the boasted panacea for the evils of that clumsy and antiquated contrivance, the coroner's court. Is not the diminished number of inspections a natural result of the medical acumen now brought into play by the new coroner? Do not his acquirements enable him to decide when such an examination is necessary, and when not, while poor Mr. Baker is obliged to rely upon, and take this means of obtaining, the opinions of others? But, sir, who are those others? They are the medical witnesses, the legitimate sources of the opinions which ought to influence the jury, and I consider it an intrusion upon the part of the coroner, when he permits his own opinions to interfere with the full development and expression of those of such witnesses. The case would be different if the coroner were a medical man, exclusively devoted to this description of inquiry, although he would be even then much more properly employed as an official witness than as a coroner,' who, being in fact a judge, should content himself with laying the facts distinctly before the jury. I believe the race of Admirable Crichtons is extinct, and I cannot see how the numerous employments, political, editorial, and otherwise, allow Mr. Wakley time for that study and attention to the subject of medical jurisprudence, which would be absolutely necessary for the due fulfilment of the dictatorial part he seems so desirous of enacting.—I am, sir,

Your obedient servant,

JOHN CHATTO.

Leigh St., Burton Crescent,
Oct. 30th, 1840.

[We cannot help thinking that letters such as the above ought in the first instance at all events to be sent to Mr. Wakley.—ED. GAZ,]

WARRANT

REGULATING THE APPOINTMENTS AND PAY OF ARMY MEDICAL OFFICERS.

VICTORIA R.—Whereas it has been represented unto us, that the rank of assistant inspector of hospitals can be dispensed with; and that with a view to extend the means of promotion in the medical department of our army, it is expedient to institute a second class of staff surgeons, who shall, in rank and pay, correspond and be on a footing with the regimental surgeons, and at the same time to improve the pay and advantages of the first or superior class of staff surgeons.

We are therefore pleased to direct, that from and after the date of this our warrant, all former rules and orders respecting the titles, ranks, periods of service, and pay of the medical officers of our army, shall cease and determine, and that this our warrant shall, from and after the 1st day of October, 1840, be considered the sole and standing authority upon the subject.

1. The medical officers of the army are in future to be distinguished by the following ranks and communions, viz. :—Assistant surgeon, regimental surgeon, and staff surgeon, 2d class; staff surgeon, 1st class; deputy inspector general of hospitals; inspector general of hospitals.

2. ASSISTANT SURGEON.—No medical candidate who has not passed his examinations at the Royal College of Surgeons of London, Edinburgh, or Dublin, shall be eligible for this commission, and the assistant-surgeon must have served on full-pay five years before he shall be elegible for promotion to the rank of regimental surgeon, or of staff surgeon of the second class.

3. Regimental surgeons and staff surgeons of the second class must have served ten years in the army on full pay before they shall be eligible for the next step of rank.

4. A staff surgeon of the first class must have served three years at home, or two years abroad, in this rank, before he shall be eligible for promotion.

5. A deputy inspector-general of hospitals must have served five years at home, or three years abroad, in this rank, before he shall be eligible for promotion to the highest rank of inspector-general.

6. The rates of daily pay for the before-mentioned ranks are to be in future regulated by the length of time which the officers of each class shall have served upon full-pay according to the annexed scale; provided always, that when any officer is hereafter promoted, he shall commence upon the *minimum* pay of his new rank, notwithstanding his length of service, agreeable to the said scale, may have given him a claim to a higher rate of pay, as before he shall be allowed such higher rate of pay he will be required to serve on each inferior rate of pay attached to his rank the following period— viz. one year, if he had been in the medical department antecedently to the 29th of July, 1830, and two years if he received his first medical commission subsequently to that date; but if the officer thus promoted had higher pay in his old rank then the *minimum* of his new rank, he shall commence upon that rate of pay which may be next above his former pay, and before he obtains any further increase shall serve the period above prescribed, viz. :—

RANKS.	Rates of Daily Pay subject to the above Provisions.			
	After 25 years' actual service.	After 20, but under 25, actual service.	After 10, but under 20, actual service.	Under 10 years' actual service.
	£. s. d.	£. s. d.	£. s. d.	£. s. d.
Assistant Surgeon	0 10 0	0 10 0	0 10 0	0 7 6
Regimental Surgeon and Staff Surgeon, 2d class	1 2 0	0 19 0	0 15 0	0 13 0
Staff Surgeon, 1st class	1 4 0	1 2 0	0 19 0	—
Deputy Inspector-General of Hospitals	1 10 0	1 8 0	1 4 0	—
Inspector-General of Hospitals . .	2 0 0	1 18 0	1 16 0	—

7. In addition to the pay of their ranks, the officers at the head of the medical department on foreign stations shall receive allowances at the undermentioned rates when serving under the following circumstances, viz. :—

If with an army in the field of 10,000 men or upwards . . . . . . 20s. a day.

Ditto. . . . 5,000 ditto 15s.

Ditto. . . any less number 10s.

If serving in a colony where the force consists of 1,500 men, or upwards . . . . . 5s.

Given at our Court, at Windsor, this 14th day of October, 1840, in the fourth year of our reign.—By Her Majesty's command,
T. B. MACAULAY.

POISONING WITH ARSENIC AND ANTIMONY.

EXPERIMENTS BY M. ORFILA.

M. ORFILA commenced his experiments in one of the amphitheatres of the Faculty of Medicine, before a special commission of the Academy of Medicine and a numerous audience. The professor made a number of experiments on poisoning by arsenical acid and tartar emetic, and, by the programme which he distributed, undertook to prove —

1. That arsenical acid and tartar emetic introduced into the alimentary canal, or placed on the subcutaneous cellular tissue, are absorbed, mingled with the blood, and carried through all the organs of the animal economy.

2. That they remain for a certain time in the viscera and muscles, where their presence is demonstrated ; but that, from the time of the poisoning, a part of the portion which is absorbed leaves these tissues, and is eliminated by the urinal process.

3. That this elimination, which is much more rapid in case of tartar emetic than of arsenical acid, continues during several days, until the tissues in question have been completely freed from the presence of these poisons.

4. That it is therefore advantageous, and even indispensable, in the treatment of poisoning by poisonous substances, to favour the secretion of urine.

5. That it is possible, in most cases, to distinguish whether the arsenical acid and tartar emetic which are withdrawn from the viscera of the human corpse have been absorbed during life, or have entered those viscera through "cadaveric imbibition" after death.

6. That the most fitting process for detecting small quantities of those absorbed poisons, consists in destroying the major part of the entire of the organic matter, by carbonizing them with concentrated azotic acid, or decomposing them with azotate of potash, and introducing the products into Marsh's apparatus modified.

7. That it is always easy to distinguish arsenic from antimony through the form of spots, and to be quiet certain that those spots proceed neither from the apparatus nor the chemical agent employed.

8. That there exists in the bones both of man and of several animals, an arsenical compound insoluble in water.

9. That from the muscular flesh of the human body may be extracted a matter which M. Orfila believes to be formed of an excessively small proportion of arsenic, sulphur, and an organic substance.

10. That in the earth of certain cemeteries there are found quantities, infinitely small, of arsenic, which boiling water will not dissolve.

11. Finally, that it is easy, in a legal inquiry, to avoid those errors which would appear at first sight to spring from the admitted fact of the presence of arsenic in human bones and muscles, and in the earth of certain cemeteries.

M. Orfila then proceeded to make his experiments. Several dogs were poisoned ; some by the introduction of 12 grains of arsenic in tartar emetic into the stomach, others by inoculating them under the skin with an infinitely small quantity of these poisons, imbibing it through the vessels being found a much more ready mode than absorbing it through the digestive or-

gans. Upon the death of these animals, which was expected to take place in 24 hours, ulterior experiments would take place. After having explained the theory of Marsh's apparatus, and satisfied himself and his audience as to the purity of the reactions which he meant to employ, M. Orfila proceeded with his comparative proofs upon the remains of two dogs, one of which had not taken arsenic, and the other had died at the expiration of three hours, after receiving a quantity of arsenic into his stomach, preliminary precautions having been taken against vomiting, and against the action of the urinal process. The following results were obtained :—

1. The urines of the dog, which had not been poisoned, yielded, when submitted to Marsh's apparatus, manifest signs of arsenic, while those of the dog which had been killed by suspension, without poison being administered, did not exhibit one atom of it.

2. A very small portion of the liver of the poisoned animal, subjected to a preliminary treatment by suitable chemical porcesses, and afterwards exposed to Marsh's apparatus, yielded multiplied spots of arsenic, while the entire liver, lungs, spleen, and heart of the dog killed by suspension, on being submitted to the same chemical treatment and reactions, did not exhibit the smallest trace of arsenic.

MENSTRUATION DURING GESTATION, AND AMENORRHŒA IN THE INTERVALS.

By Dr. MEURER.

A WOMAN, æt. 27, and now for the fourth time pregnant, has always had her menses regularly during pregnancy, and only during that time. They come on without any illness; and she has always borne healthy children at the full period. While unmarried, and except during pregnancy, she never menstruated, but she was never unwell from it. Her general appearance is rather masculine; it appears, therefore, that in her, as in all viragos, the sexual functions require a powerful excitant, such as pregnancy, to make them be energetically performed. The menstruation appearing in such a person during pregnancy may be regarded as a wise effort of nature to relieve the local fulness of the sexual organs, which might prove injurious.—*Med. Correspendenzblatt.* Bd. 9. No. 31.

SPONTANEOUS TURNING.

By Dr. THUMEN, OF PRENZLAU.

THE author was to attend a woman whom he had delivered on two former occasions. Two midwives assured him that the head of

the child had presented properly, but had retired an hour previously, when the woman overpowered by pain had violently thrown herself round in bed, an action which was followed by much hæmorrhage. Since then she had complained of unbearable pain in the whole abdomen, and the whole left side, in particular, was excessively tender ; the pulse small, and from 120 to 130 ; the face pale and sallow ; the eyes were sunken ; and there was frequent vomiting. On examination, neither os uteri, nor vaginal portion of the uterus could be reached, but much dark blood rushed forth. The author apprehended a rupture of the uterus. On introducing his whole hand, he reached the os uteri, which was high in the pelvis and much dilated, but entirely closed by the placenta. Passing by the placenta and the breech of the child, he was easily enabled to grasp the feet, which lay forwards, and thus rapidly complete the turning. The child lived, and the mother remained well. The pains entirely ceased in two days.—*Med. Zeit.* and *Schmidt's Jahrbücher.*

MISCELLANEOUS CASES.

Myelitis rheumatica. — (Rheumatic inflammation of the spinal marrow.) Dr. Olzewski misinterpreted the symptoms, which severally indicated pneumonia, hepatitis, and bronchitis, until the case was cleared up by the position of the patient, who lay constantly stretched out at length on his back.

Hypertrophy of the liver.—This case was cured by Dr. Olzewski with moxa and foot-baths containing nitric acid. The patient was thirty old years old, and the disease had probably been caused by an ague.

Spasm of the chest.—The same physician cured this disease, which occurred in a violent form in a woman aged 82, and resisted all other remedies, with the fused nitrate of silver. He gave one-thirtieth of a grain a day, and four grains effected a cure.*

Bite of a viper.—Dr. Weger gives a case where this was followed by inflammation of the tongue and the neighbouring parts. The affected organs swelled to such a degree, that tracheotomy was necessary to prevent suffocation, and the patient was then saved by bleeding, scarification of the tongue, &c.

Diabetes mellitus.—Dr. Graef narrates a fatal case of this disease. In five weeks the patient consumed 150 grains of opium, and took ammoniated copper for seven weeks, but without advantage.—*Schmidt's Jahrbücher,* from the Reports of the Royal Medical College at Königsberg.

* The small dose in the text is not very likely to discolour the skin ; but we think this remedy ought never to be administered internally, without warning the patient of the possibility of the occurrence, and obtaining his consent to the risk.—*Translator's note.*

STRABISMUS.

DATE OF MR. LUCAS'S OPERATION.

To the Editor of the Medical Gazette.

Sir,

Your last number of the MEDICAL GAZETTE contains a letter in which I am charged with the novel and serious offence of attempting to substitute one date for another, in my account of the first case of strabismus on which I operated; I have, therefore, to request the favour of your inserting in the forthcoming number of your journal the accompanying letters; and I also beg to say I shall not trouble you with any further communication on this subject. — I am, sir,

Your obedient servant,

P. BENNETT LUCAS.

12, Argyle Street, Nov. 11, 1840.

Copy of my letter to Dr. Hingeston and Mr. Wardrop, Jun.

9th Nov. 1840.

My Dear ——,

If your memory serves you, pray oblige me by stating, in answer to this, the day on which you asssisted me in the operation upon Catherine Culbert. — Ever yours,

P. B. LUCAS.

12, Argyll St.

Dear Mr. Lucas,

I perfectly recollect the case of Catherine Culbert, on whom you operated for strabismus, and in which Dr. Hingeston and myself assisted you. The date of the operation as reported in the Lancet, viz. April 7th, 1840, is perfectly correct.

Yours very sincerely,

JAMES J. M. WARDROP.

Charles St., St. James's,
November 10th, 1840.

19, Queen's Buildings,
Brompton Road,
11th Nov. 1840.

My Dear Lucas,

Having assisted you in the operation upon Catherine Culbert, during which I suggested a deviation from Dieffenbach's mode of operating, I read the report of her case in the Lancet at the time with attention, and was satisfied as to its correctness in all particulars, so that I feel convinced that the date is there rightly stated. – Yours truly,

ROBERT HINGESTON.

[Any farther communication on this subject, from either gentleman, must be inserted in the *extra limites* department.—ED. GAZ.]

MEDICAL APPOINTMENTS.

Dr. P. Black and Dr. Goolden have been appointed Physicians to the Dreadnought Hospital Ship, in the room of Dr. George Budd, who had resigned on his appointment to the Professorship of Medicine at King's College.

Mr. H. Thompson, at present Assistant Surgeon, succeeds Sir Anthony Carlisle as Full Surgeon to Westminster Hospital, nearly as a matter of course.

Several gentlemen have started for the office of Assistant Surgeon, among whom are Mr. Malyn and Mr. Guthrie, Jun.

The Governors of Middlesex Hospital have decided on having an Assistant Physician : we observe Dr. Leighton in the field.

ROYAL COLLEGE OF PHYSICIANS.

THERE have been elected to the fellowship— J. Hope, and C. J. B. Williams.

Have passed to the fellowship from the list of candidates — G. E. Paget, Henry Powell, Mervyn A. N. Crawford, R. N. Goolden, Alexander J. Sutherland.

Have been admitted as licentiates—James Bovell, Henry Bell, Anthony Yeoman, Thomas Smith, J. N. Porter, Anthony T. Carpenter, Richard Oliver, William Strang, Thomas West, George R. Rowe, J. Ogden, Morris Pritchett, Thomas O. Prichard, Robert T. Allaway, John G. Stewart, Frederick B. White.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, November 6, 1840.

H. Julian.—H. A. Duncan.- A. C. Robertson. —W. C. Calthrop.—A. E. Turnour.—J. H. Partridge.—A. Kitt.—W. H. Scales.—G. Downing. —G. Fizey.—W. C. Williamson.—R. D. D. Allan.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, November 5, 1840.

John Dixon Fidler, Whitehaven.—J. Deacon, Sheffield.

METEOROLOGICAL JOURNAL.

Kept at EDMONTON, Latitude 51° 37' 32" N. Longitude 0° 3 51' W. of Greenwich.

Nov.	THERMOMETER		BAROMETER.	
Wednesday 4	from 42 to 53		29·21 to 29·32	
Thursday 5	46	51	29·18	29 24
Friday . . 9	39	51	29·10	28·94
Saturday . 7	45	54	29·10	29 17
Sunday . . 8	38	53	29·25	29·32
Monday . . 9	42	51	29·08	29·09
Tuesday . 10	40	53	29·04	29·24

Winds S.W. and S.E.

On the 4th, morning cloudy, with rain ; otherwise clear. The 5th, morning and evening cloudy, with rain ; afternoon clear. The 6th cloudy, with frequent showers. The 7th generally clear, except the morning, when rain fell heavily. The 8th and two following days generally clear. A shower of rain on the morning of the 9th.

Rain fallen, ·93 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE IX.

*Inflammation. Its morbid and its salutary
effects. Sketch of the local and consti-
tutional phenomena of inflammation as it
occurs in external parts. Examination
of the symptoms of inflammation ; pain ;
heat ; redness ; swelling. State of the
capillary blood-vessels, and of the blood
in a part inflamed.*

INFLAMMATION must needs occupy a large
share of the attention both of the surgeon
and the physician. In nine cases out of
ten the first question he asks himself upon
being summoned to a patient is, " have we
inflammation here ?" It is continually the
object of his treatment and watchful care.
It affects all parts that are furnished with
blood-vessels, and it affects different parts
very variously. It is more easily excited by
many external causes, and therefore it is
more *common* than any other special dis-
ease. A great majority of all the diseases
to which the human frame is liable begin
with inflammation, or end in inflammation,
or are accompanied by inflammation during
some part of their course, or resemble in-
flammation in their symptoms. Most of
the organic changes of different parts of the
body recognize inflammation as their cause,
or lead to it as their effect. In short, a
very large share of the premature extinction
of human life in general is more or less
attributable to inflammation.

Again, inflammation is highly interesting
not only in its morbid phenomena and destruc-

tive consequences, but in its healing tendencies
also. It is by inflammation that wounds are
closed, and fractures repaired—that parts
adhere together when their adhesion is es-
sential to the preservation of the individual
—and that foreign and hurtful matters are
conveyed safely out of the body. A cut
finger, a deep sabre wound, alike require
inflammation to re-unite the divided parts.
Does ulceration occur in the stomach or
intestines, and threaten to penetrate through
them ? Inflammation will often anticipate
and provide against the danger—glue the
threatened membrane to whatever surface
may be next it—and so prevent that worse
and universal inflammation of the peritoneum,
and the almost certain death, which the
escape of the contents of the alimentary
canal into that serous bag would infallibly
occasion. The foot *mortifies;* is killed by
injury or by exposure to cold :—inflam-
mation, if it be not anticipated by the knife
of the surgeon, will cut off the dead and
useless part. An abscess forms in the liver—
or a large calculus concretes in the gall-
bladder : how is the pus or the stone to be
got rid of ? If they make their way to the
external surface of the organ, as they always
tend to do, they enter the cavity of the
abdomen, and excite fatal peritonitis. But
a natural safeguard arises ; partial inflam-
mation precedes and prepares for the expul-
sion ; the liver or the gall-bladder, as the
case may be, becomes adherent to the walls
of the abdomen on the one hand, or to the
intestinal canal on the other ; and then the
surgeon may plunge his lancet into the col-
lection of pus—or the abscess or the calculus
may eat their own way safely out of the
body—through the skin, or into the bowel.
Inflammation, limited in extent and mode-
rate in degree, becomes conservative by
preventing inflammation more severe and
more widely spread, which would be fatal.
This is what I mean when I speak of the
curative properties of inflammation ; and

X

surely this process, which may save life or destroy it, deserves and demands our most careful study.

But inflammation has a still farther and peculiar claim upon our attention. The salutary acts of restoration and prevention just adverted to, are such as *nature* conducts and originates. But we are ourselves able, in many instances, to direct and control the effects of inflammation—nay, we can excite it at our pleasure ; and having excited it, we are able, in a great degree, to regulate its course. And for this reason it becomes in skilful hands an *instrument of cure*. This instrument the surgeon employs when, after letting out the water of a hydrocele, he wilfully excites inflammation of the tunica vaginalis, which obliterates its cavity, and renders the reaccumulation of the fluid impossible. It is by availing himself of the same agent that he is enabled to remedy many afflicting deformities :—to unite the cleft lip ; to close up the fissured palate ; to restore the dilapidated nose. There is no other special disease which is thus at our command ; we cannot, if we would, produce a tubercle or a cancer. For all these reasons inflammation possesses a very high degree of interest for us—and for every one who would enquire, with any prospect of success, into either the pathology or the treatment of diseases.

Of the amount of our knowledge respecting the *intimate nature* of inflammation, I shall have occasion to say a few words by and by. We first become acquainted with inflammation in its symptoms, and as it displays itself externally. After we know what they are, it may be right, and cannot but be interesting, to enquire how they come about. Now the symptoms which, when they exist together in an external or visible part, betoken or denote inflammation of that part, are four in number : pain—redness—heat—swelling ; *preternatural* redness, and *preternatural* heat. These, from the earliest ages, have been recognized as the signals of outward inflammation. " Notæ inflammationis (says Celsus) sunt quatuor—rubor et tumor cum calore et dolore."

No definition, however, or general description, can be made to embrace all the forms in which inflammation presents itself. We can give no useful account of it in the abstract ; and therefore I shall first sketch the phenomena of inflammation under one of its most common external forms ; and taking this as a type of the disease, proceed afterwards to trace its modifications and varieties, and to fill up the picture.

Let us suppose, then, that a healthy man receives some local mechanical injury—that he falls, for instance, against a window, and gets a piece of glass stuck into his arm. In a short time he begins to have pain in that part of the arm, and this is soon succeeded by redness, and increased heat, and swelling. The skin becomes of a bright red colour ; the swelling increases. In the immediate place of the injury the swelling is firm and hard, and exquisitely tender : at some distance from that centre, although there is still swelling, the parts are softer and more yielding. In the seat of the redness and swelling the patient experiences a sense of heat, a burning pain ; the part is sensibly hotter than natural to the touch of a by-stander ; and if its actual temperature be measured by means of a thermometer, it will be found to exceed the temperature of the neighbouring surface. *The part is inflamed*. This is what is called phlegmonous inflammation. φλεγμονη is a Greek word, and *inflammatio* is a Latin word, and they both mean the same thing, viz. a burning, or a flame. Phlegmonous inflammation is therefore, in truth, a tautological phrase. But custom has assigned a particular signification to the epithet phlegmonous ;—it denotes that kind of violent inflammation in which the inflamed part seems all on fire.

If the inflammation reach a certain degree of intensity, other signs of disorder present themselves at a distance from the injured spot. The patient usually at first feels chilly and feeble ; but soon the temperature of the whole of the surface rises, the skin becomes hot and dry, the pulse more frequent and fuller and harder than is usual ; lassitude comes on, and headache, and wandering pains in the limbs. The patient is unable or unwilling to exert himself, and finds that he is unapt for any mental effort ; he cannot command his attention, gets confused and restless, and sleeps ill ; he loses his appetite, his tongue becomes white, his mouth is parched, he is unusually thirsty, and the various secretions of the body are deranged and diminished.

This is *inflammatory fever*. This is an *indirect symptom* of inflammation, manifesting itself *through the medium of the system at large*. Various names have been given to this general disturbance of the vascular and nervous systems : constitutional disturbance — sympathetic fever — symptomatic fever. It matters little what term is used, provided that we affix always the same meaning to it : but inasmuch as the word *fever*, in this and in other languages, is taken to express a specific disease, it would perhaps be better to employ the term *pyrexia*, as Cullen and others have done, to denote that secondary febrile state which grows out of, or is associated with, primary local inflammation.

Now what is the end of this remarkable state of things ? Why, it may end in one of two or three different ways. Supposing the

piece of glass to be extracted, and proper measures to be taken for subduing the inflammation, or even supposing that no other measure is adopted except removing the bit of glass, then it will often happen that the phænomena just described will gradually recede and disappear ; the pain will abate, the redness fade, the swelling diminish, the heat decline, the pyrexia cease ; until the part at length regains its usual sensations and its natural appearance. When inflammation subsides in this way it is said to be *resolved*, to terminate by *resolution :* and this is its most favourable and desirable mode of terminating, whenever inflammation occurs as a morbid process.

But in many instances the inflammation does not thus subside. The irritant cause still remains in action—or the original intensity of the inflammation has been too great to admit of resolution—or the means proper to abate it have not been used—or have not succeeded. The symptoms already described continue, and are aggravated in degree : at length the swelling begins to assume a more projecting and pointed form, and the skin in its centre to look white ; the central part of the swelling, formerly so hard, becomes softer—the pain is of a throbbing kind : a pulsative sensation, keeping time with the beats of the heart, is experienced in the part, and often a feeling occurs as if something had given way within it : at last (if art does not interpose) the cuticle breaks, and a yellow cream-like fluid is poured out, which we call pus, and upon its escape there generally ensues a considerable and speedy abatement of all the local symptoms of inflammation—of the pain, the heat, the redness, the tumor.

This is *suppuration.*

Meanwhile, especially if the suppuration be long continued, and the discharge of pus profuse, the character of the general febrile excitement undergoes a change. Slight but frequent shiverings, or feelings of chilliness, take place, followed by flushes of heat, which end in perspiration.

This is *hectic fever.*

If the injury has been still more serious, and the inflammation more intense, the part that it has invaded perishes by the violence of the disease ; there is partial death. In that case the vivid red colour alters to a purplish or livid, or even a black, or greenish-black hue, the tension of the part exists no longer, the cuticle is elevated by a sanious fluid, the pain ceases, the part is devoid of all sensation—is dead and putrid, and exhales a peculiar and offensive odour.

This is *mortification.*

When the injury has been extensive, a corresponding and characteristic change is again observable, sometimes in the constitutional febrile disturbance. The patient grows more and more feeble, and delirious ; he has involuntary startings of the tendons of the voluntary muscles—his pulse is weak and very frequent — his tongue becomes dry, brown, tremulous—his lips are black with accumulated sordes—his countenance is shrunk, haggard, ghastly—his stools and urine escape from him without his appearing to be conscious that they do so.

This is *typhoid fever.*

Under more favourable circumstances the dead or mortified part, which is called a slough, separates from the living parts, and leaves a breach of surface. The separation is effected by a vital process which is denominated *ulceration ;* but which I need not now describe. The cavity thus formed gradually fills up, and heals in a peculiar way.

There is one other circumstance, not to be omitted in this rough outline of the local and general phenomena and effects of inflammation. If during its progress blood be drawn from a vein, it exhibits, after standing and coagulating, the peculiar appearance known by the name of the *buffy coat ; i. e.* on the surface of the coagulum, and to a certain depth in its substance, the colouring matter of the blood leaves the fibrin, which is therefore seen of a yellowish hue, or buff colour.

Taking the preceding statement as a groundwork, let us look back upon it, and trace its particulars a little more in full. The four characteristic signs of inflammation being pain, heat, redness, and swelling, it will be useful to examine each of these symptoms more closely, in its turn.

The *pain* varies much in different cases of inflammation, both in degree and in kind. It is differently felt, *cæteris paribus*, by different persons, according to their natural susceptibilities. It varies from the slightest degree of sensibility to the utmost agony and torment Parts which, when sound, are endowed with little or no sensation (as tendons, ligaments, cartilage, bone), become often exquisitely sensible under inflammation. The organs of sense are variously affected in this respect : thus the specific sensibilities of the mouth and nose are blunted by inflammation—those of the eye and ear are often rendered painfully acute.

There are great diversities also in the kinds of pain. Sometimes it is of a dull aching character, as in toothache ; sometimes it is a pricking, tingling, smarting sensation : this is the case in some forms of inflammation of the skin, as in erysipelas for example, and in herpes ; sometimes it is sharp and piercing, as if the part were stabbed or cut with a knife—such is frequently the case in inflammation of the serous membranes, in pleurisy for instance ; sometimes the pain is tensive or stretching ;

and sometimes there is scarcely any pain at all. This last chiefly happens in the mucous membranes and in the parenchymatous texture of organs. Very often the pain is a ' bulking" or throbbing pain – every beat of the heart makes itself felt in the tender part. The pain of inflammation results, no doubt, from the implication of the nerves in the diseased process. The stretching of the vessels and textures adds to the pain. Every body who has been plagued by boils (and few escape them) has had proof of this : the pain is most harassing a short time before the ripening little tumor gives way, or is laid open by means of a scalpel ; but as soon as the distension is thus relieved, perfect ease and comfort ensue. It is the same in common ear-ache. It is upon this principle, I believe, that the differences in regard to pain, which occur in different structures under inflammation, are partly to be explained. Speaking generally, there is more pain felt in external inflammations, and in the inflammations of *investing* membranes, than in inflammation of the substance of the viscera, or of the *lining* membranes : and it has been conjectured that this may be because, in the latter cases, the parts affected have fewer nerves of common sensation. But I do not think this explanation satisfactory. If it were well founded we should not have such exquisite pain in some of the textures already mentioned, which appear to be furnished with very few nerves of common sensation, and scarcely feel at all in their healthy state : tendons, ligaments, and cartilages, I mean. I think it will be found that most pain is felt in those parts which are least capable of yielding—in which the tension produced by the swelling, or the tendency to swell, is the greatest. The substance of the liver, spleen, and viscera generally, is soft and yielding — the mucous membranes are spongy in their texture, and often attached to the subjacent parts in loose folds, and they allow of an accumulation of blood within them without becoming much stretched, or very tense. The investing serous and fibrous membranes are more tightly applied, and much less capable of yielding : and their inflammation is usually attended with severe pain.

The pain that belongs to inflammation sometimes precedes any other apparent change. This is especially observable in respect to internal parts. Sometimes the pain is continued and uniform. Sometimes it is continued, but irregular in severity, having periods of great exasperation : sometimes again it is intermittent, and even periodic.

It is an unsettled question that has often been mooted, whether, in inflammation, the state of the blood-vessels is determined by that of the nerves, or the reverse. Mere

nervous pains are known sometimes to be followed by congestion of the part in which they are felt. Whatever may be the true state of this question of priority, it is certain that the disordered condition of the blood-vessels, when produced, greatly augments the sensibility of the part. We may suppose that this depends, partly on over distension and stretching of the vessels and fibres, partly on pressure made upon the nerves by the swelling.

It is important to remark of the pain belonging to inflammation, that it is usually *aggravated by pressure :* frequently it is not felt at all, except when pressure is some how made upon the affected part—intentionally by the medical man – or accidentally, from the movements or position of the patient. This is *tenderness.*

And this is a point which requires a little farther notice. I say the aggravation of the pain by pressure is an important circumstance, because it continually helps us to distinguish pain that is inflammatory from pain that is not inflammatory. Thus pain of the abdomen may result from colic, or spasm—from a distension of the intestines by air, and a stretching of the textures and nerves belonging to them : and this sort of pain will mostly be relieved by pressure ; you will find patients lying upon their bellies across the back of a chair for the sake of obtaining ease : but if the pain proceed, as it may, from inflammation of the peritoneum —oh ! then the gentlest pressure, even that of the superincumbent bed-clothes, causes intolerable torture. The *suddenness* with which the pressure is made—and its being made on a *part* only of the suffering organ— these circumstances have much to do with the augmentation of the pain ; and it is curious, and instructive too, to know that *gradual* pressure, applied *uniformly* to the *whole* organ or part under inflammation, is sometimes so far from enhancing the pain, that it relieves or removes it. Dr. Elliotson puts a very good case in illustration of this. " If (he says) you have a blister upon the sole of the foot, or at the ball of the great toe, and you rest gradually upon the part, the pain becomes mitigated, till at last it seems to be almost entirely removed ; but the moment you take off the pressure, and raise the foot from the ground, you feel the part begin to throb—to throb with violent pain."

Now all this exemplifies what I said just now—that though a deranged condition of the nerves, marked by pain, may, for aught I know, first lead to the vascular fulness— yet that fulness, and the distension which it implies, will greatly increase the pain. In fact, the expulsion of the blood by means of well-regulated pressure is made the foundation of certain proposed methods of cure. This has been lately recommended in hernia

humoralis, or swelled testicle—what is now more scientifically called orchitis. It gives one a sort of horror even to think of pressure being made on the healthy testicle—much more when it is rendered preternaturally sensible by inflammation: yet when properly managed it is said (by Dr. Fricke, of Hamburgh, and others) not to increase the pain, but entirely to remove it, so that the patient can at once walk about the room ; and the disease is thus ultimately cured. In the same way it has been proposed to cure erysipelas, and gout, and rheumatism. I don't enter here into the expediency of such me asures ; but mention them in illustration of the various effects of pressure in various circumstances, upon inflamed parts. Certainly it must be dexterously and fortunately managed not to do harm ; not to make matters worse ; and if there be already much *extravasation* of any kind, I should think that pressure, however regulated, would be peculiarly likely to increase the pain and the mischief.

It is sometimes necessary to recollect, especially when the existence of internal inflammation is suspected, that all expression of the sense of pain, and probably all sensation of pain, may be prevented or abolished by the presence of stupor or *coma*. So also, if the nervous connexion between the inflamed part and the sensorium be cut off, no pain is felt. Limbs in a state of palsy are often (though not always) destitute of sensibility also ; and inflammation readily occurs in them, but is attended with no pain.

That *mere* pain will not constitute inflammation must I think be plain to you. Spasmodic contractions of the muscles, stretching and tension of the tissues, a particular state of the nerves, and sundry causes that do not imply inflammation, may nevertheless be attended with severe pain.

Let us next consider the *heat*.

Of course, as I hinted before, this means *preternatural* heat : the temperature of the part exceeds that which belongs to it in health ; but in truth, the heat is not in general so much increased as the sensations of the patient, or his heightened sensibility, would persuade him it is, or even so much as a by-stander might suppose. The heat of inflammation does not rise above the maximum heat of the blood in the central parts of the body. The natural heat of the blood is about 98 or 100°, but in fevers and inflammatory diseases it has been known to reach 107°, and the maximum heat of the blood in fever is probably the limit of the temperature as it exists in inflamed parts. The surface of the body, in its natural state, is not quite so warm as the internal parts, and the extremities are generally less warm than the trunk ; so that the contrast between an inflamed and a healthy part, in respect to

heat, is greater in the extremities than on the trunk. Thus if a blister be placed upon the chest, the heat of the part inflamed by its application will not exceed that of the neighbouring healthy surface by more than a degree or two ; while a blister applied upon the leg may occasion a difference of 5 or 6°. John Hunter took great pains to ascertain the degree of heat produced in inflammation. He excited inflammation in the cavity of the thorax of a dog, and in the vagina and rectum of an ass, and he could not find that the temperature of the parts thus inflamed ever exceeded that of the blood at the centre of the circulation. He did not neglect the opportunities that came before him of making similar observations on the human body. He had occasion to tap a patient in St. George's Hospital for hydrocele : as soon as he had let the fluid out, he introduced a thermometer through the puncture made by the trocar, and placed it in contact with the testicle. He found the temperature to be 92°. He repeated this experiment the next day, when inflammation had set in, and then the thermometer rose to 98¾°. So that here an increase of 6¾° had taken place in consequence of the inflammation ; but even this, you see, did not go beyond the natural warmth of the blood.

It may be presumed that the increase of heat depends mainly upon the increased influx of blood into the part. Possibly some vital actions taking place under inflammation tend to develope it, but it is a curious fact, a fact worth remembering,[1] that the heat of inflammation does not transgress or surpass that of the blood in the central parts of the body.

Heat alone does not constitute inflammation, for parts of the body may be made preternaturally hot by holding them before the fire, by friction, by exercise, while there is no inflammation.

I apprehend that increased heat is essential to inflammation, in some stage or other of its progress, although there are cases in which the augmented temperature is not perceived or appreciated. Sometimes the increase of heat is very slight, and may be easily overlooked, there being nevertheless unequivocal inflammation ; redness and swelling, which go slowly into suppuration. The heat is often concealed from the observation of the physician or the surgeon, by the situation of the part affected, and it escapes the notice of the sufferer, because the sensibility to heat is less generally diffused through the body than the susceptibility of common sensation. The heat of inflammation is usually less felt and less complained of by the patient than the pain. A vivid sensation of heat *is* pain.

The *redness* of inflammation must also be *preternatural* in degree, for many parts of

the body are by nature, and in health, more or less red. This phenomenon depends upon the greater quantity of blood contained in the vessels of the part, and sometimes also upon the extravasation of a portion of the blood into the affected texture. There is more blood than usual in those vessels which naturally carry red blood; red blood enters too into vessels which in the healthy state are destined to receive and convey colourless fluids only, or which naturally admit so *few* of the red particles, that from their paucity, and the quickness of their motion, they cannot be seen. We are sure of this from what takes place in ophthalmia. Doubtless also the redness is sometimes increased by the formation of *new* vessels that admit the colouring particles of the blood in visible numbers.

That the vessels which naturally circulate red blood are actually distended and enlarged in inflammation, there can be no doubt. John Hunter (whose treatise on Inflammation is a mine in which all succeeding writers have dug) excited inflammation in one of the ears of a rabbit, and then killed the animal. He next injected the head and ears from the aorta, so that the fluid injected passing through both the carotids, was driven in equal quantities and with equal force towards each ear. The arteries of the inflamed ear were enlarged one-third beyond their natural size, and arteries in it were injected that were not visible in the sound ear. That the apparent increase in the number of blood-vessels is often owing to the circumstance that red blood enters tubes which already existed, but did not previously admit the colouring matter or did not admit it in sufficient quantity to be visible, is evident from the *rapidity* with which the redness may be produced in many textures : in the eye, for example, it may be effected in a few seconds ; and many of the vessels which become suddenly apparent are evidently *continuations* of the trunks that could be seen before.

There is much variety in the tint of the redness of inflammation, depending on the kind and degree of the inflammation, and on the nature of the part affected. Sometimes the redness is bright and vivid, as if the part were full of arterial blood ; this generally happens in the acuter forms and the earlier stages of inflammation. Sometimes the redness is dark, or livid, or purplish, more as if the part were gorged with venous blood : this occurs in some of the chronic and sluggish forms of inflammation, and it is often the case when there is a tendency to gangrene. Sometimes the redness is distinctly circumscribed, or in patches ; and sometimes it is diffused in a general blush over a large space.

The redness may, and often does, remain for some time after the inflammation has ceased.

Now seeing that redness accompanies inflammation of the external parts, we presume that it exists also in internal inflammation : indeed we may convince ourselves that it is so. If a portion of intestine be drawn out through a slit in the parietes of the belly of a dog, and suffered to remain exposed to the air, it will soon inflame, and, inflaming, it grows red. We see also that internal parts are *left* red after death, which parts we have other reasons for knowing had been inflamed during life ; and we infer that redness may have been present during life, although we find none remaining when the body is examined. That when it has been owing to mere fulness of the natural blood-vessels, it may disappear with parting life we know, because the same thing happens externally, as in erysipelas and scarlet fever : but in such cases the inflammation has not gone to any great height.

It is proper to remark that as the absence of redness is no proof that there has not been inflammation, so its presence is no proof of the contrary. There are many kinds of redness, both within the body and on its surface, that have nothing to do with inflammation : yet some of these are very apt to be mistaken for traces of inflammation. I shall endeavour to instruct you how to avoid such a mistake, when we come to examine the morbid anatomy of particular forms of disease.

While inflammation actually exists, redness, of some shade or degree, is seldom absent, even though the other symptoms may be scarcely apparent.

Lastly, let us take a glance at the *swelling*. This also depends, in part, upon the distension of the blood-vessels ; but no great amount of swelling can be attributed to this cause ; and as much as does proceed from it occurs *early* in the disease. A part also, and usually by far the greater part, of the swelling, results from the presence of matters poured out into the interstices of the affected part. These effused matters are of very different kinds, although they are modifications of the same liquid, the blood. I mentioned, in describing the condition of the part inflamed, that the central portion of the swelling is, at first, hard and resisting, while at a greater distance from the centre the swelling is softer, and yields more readily when pressed by the point of the finger, and sometimes even pits a little under that pressure. Now the central hardness is to be ascribed to an effusion into the cellular texture of the part, of a fluid, which, transparent at first, speedily becomes opaque and more consistent, and at last assumes a solid form : this is what is commonly called, in this country, coagulable lymph. The softer

swelling at the circumference of the tumid part proceeds from the effusion of a thinner fluid, of serum, into the cellular tissue. Under very violent inflammation, blood in substance is poured out into the same parts. When the central portion of the swelling softens and becomes pointed, this part of the whole enlargement is owing to the presence of a quantity of pus. The different liquids that I have now been mentioning are of great importance, and play a conspicuous but diversified part in altering textures. Blood: serum: albuminous fluid or coagulable lymph: pus. They are called the *products* of inflammation. We are sure that inflammation has been at work if we meet with certain of these products. We are not sure there has been inflammation if we perceive mere redness :—we are not always sure if we find serum only :—we are not sure if we find blood alone :—we are tolerably certain if we discover pus ; we are certain at least that there has been inflammation *somewhere*, though doubts have been started whether the pus is not sometimes conveyed from an inflamed part to other parts of the body. We are *quite* sure that there has been inflammation in a part if we find coagulable lymph in that part. This often remains, as a monument of the inflammation, during life : it frequently becomes organized, furnished with blood-vessels, and a great number of changes, some reparative, some morbid, depend upon its presence. I shall have to recur to these *products* of inflammation hereafter.

The degree of swelling in different cases depends partly on the intensity of the inflammation, partly on the nature and texture of the structures affected.

I need scarcely observe that swelling may exist without any inflammation. Hernia, simple anasarceous enlargements, dislocations, will occur to you as every-day examples of swellings that have no necessary connexion with inflammation.

On the other hand, inflammation may exist without any *appreciable* swelling. Inflammation of the sclerotic coat of the eye, for instance, may be present, without any swelling cognizable by our senses.

We have seen, in this review of the symptoms of inflammation, how much they severally depend, the pain, the swelling, the redness, and the heat, upon the increased influx of blood *into* the part.

It may not be uninteresting to pause here for a moment to enquire what has been ascertained in respect to the actual condition of the capillaries of an inflamed part, and of the blood they contain. Much has been learned on these points by patient and minute observation with the microscope, and by reasoning upon the facts thus brought to light. Kaltenbrunner, Gendrin, Müller,

and others, have corrected many erroneous notions which formerly prevailed upon this subject.

In order to comprehend the minute phænomena of inflammation, you must have a clear conception of the constituent elements of the blood, and of the main changes it is liable to undergo. The rough anatomy, rather than the chemistry of the blood, is what I allude to.

The blood consists of red particles, or globules, and of a transparent colourless fluid called lymph, or liquor sanguinis. Müller succeeded in separating these two constituents of the blood by filtering through paper that of a frog, which contains very large red globules. The liquor sanguinis thus obtained separates spontaneously, by coagulation, into two parts, into serum and fibrin, the last having previously existed in solution in the liquor sanguinis.

When the coagulation is suffered to take place without any attempt to remove the red particles, these are entangled and enclosed in the fibrin as it becomes solid ; and the common well-known appearance of clot and serum occurs. You may even then wash out the red particles from the clot, and leave the fibrin.

I must now recur to the experiments and observations of Kaltenbrunner. I should have told you, on a previous occasion, that various stimulant substances, mechanical or chemical, when applied to the web of a frog's foot, will produce irregular disturbances in the circulation, which irregular disturbances you are not to confound with true congestion : in like manner you must avoid confounding them with the phænomena of *inflammation*, which are always preceded by those of true congestion. Kaltenbrunner found likewise, that (just as in congestion) a certain interval of time generally happened between the application of the exciting cause and the apparent development of the inflammation. This accords with what we observe to be the case in respect to local injuries, and to those local internal inflammations that are apt to be produced by exposure to cold. There is a pause before the mischief lights up : or (to take the metaphor from the eggs of birds) there is a period during which the inflammation seems to be hatching, and it is called accordingly a period of *incubation*. Kaltenbrunner describes inflammation to be a regular process—as he had also described congestion to be.

On looking then at the web, to which some violence had been done, he observed, after the first irregular disturbances were over, and when the period of incubation had elapsed—he found (I say) that an afflux of blood took place to the part about to be inflamed : the velocity of the blood in the vessels was greatly accelerated ; the vessels

themselves were distended and tense, and therefore disposed to tighten upon the blood they contained—the functions of the part, that is to say, the secretion and absorption of lymph, were interrupted; the blood underwent an evident change—or it failed to undergo the proper changes : its globules stuck together, and the parenchyma of the web became tumefied. Now all this is just what I represented to you in a former lecture as constituting the state of the blood-vessels under *active congestion ;* and I also told you, at that time, that such congestion was just one step short of inflammation. The congestion now described increases, until, at length, this remarkable alteration happens : the capillary tubes, instead of tightening upon their contents, dilate, or grow larger ; the circulation, at first so rapid, begins to be *delayed* in some of the capillaries ; the direction of its motion becomes uncertain ; it oscillates, as it were, irregularly in those vessels, and at last stops altogether, the globules cohering in irregular masses, and thus *points of stagnation* are formed ; and these points of stagnation, if the affection goes on increasing, augment in size, and multiply in number. Around them, beyond their circumference, the circulation remains still very rapid, and the congestion persists. This is *inflammation*—of which the characteristic or pathognomonic feature is the formation of these *points of stagnation.*

Now one early consequence of the stagnation of the blood is, that a portion of it transudes through the sides of the vessels containing it : the serum ; or the liquor sanguinis ; or even sometimes the blood itself, red particles and all. The effused serum remains, or is absorbed, as serum. The fibrin, when it has so transuded, concretes, and thus the interstices of tissues are filled up, and layers of coagulable or coagulated lymph are formed upon the surfaces of inflamed parts, constituting false membranes ; and under certain circumstances, already adverted to, other, or farther, changes take place : the red particles which have passed into the inflamed tissue, or which still remain stagnant in the capillaries, undergo a remarkable transformation, lose their coloured capsules, become yellow, grow larger, and are converted into globules of *pus.* So that pus is nothing else than altered blood.

But pus appears also to be formed in a more rapid manner, by a sort of secretion : it almost streams, sometimes, from the surfaces of mucous membranes. It has lately been affirmed that certain globules, visible in blood drawn during health, and larger than the rest, are pus-globules ; and that under inflammation these pus-globules mul-

tiply some how. The question must be regarded as *adhuc sub judice.*

Certainly much which used to be thought mysterious in the process of inflammation has been rendered more simple and intelligible by modern research. Most of the events or consequences of that process are traceable to the stagnation of the blood in the capillaries, and to the changes which the stagnant blood subsequently undergoes.

I must not omit to tell you what Kaltenbrunner says about the direct absorption that takes place in the inflamed part. He found that the *colouring* matter, and the *adipous* matter, were thus taken away. The web of a frog's foot is speckled over with little stars of five rays, caused by a black pigment. The extremities of these rays gradually disappear until mere black points are left in the places of the stars. He says that he has been lucky enough to catch the exact moment when the blood, circulating rapidly in the canals, has detached a particle from one of the rays, and carried it into the torrent of the circulation. In the sound state, the mesenteric vessels of the rabbit are surrounded with much fat. When the mesentery is inflamed, the adipous cells soon empty themselves : a number of capillary canals develope themselves on the walls of those cells, and it is probable that the fat is carried off by the blood circulating in these canals.

Another curious and interesting sight witnessed by Kaltenbrunner was the formation of new blood-canals. He says that in an organ recently inflamed, when the circulation is accelerated, globules of blood may be seen to sally, all of a sudden, from some capillary, pass into the surrounding parenchyma, force themselves a channel, and reach another capillary canal. Thus a new capillary channel is formed ; the blood circulates through it ; its formation is often the work of a few seconds only. As the same thing is repeated in different parts, a rich net-work of new capillary canals is added to the original set, whereby it happens that organs which in the sound state are but slenderly furnished with capillary vessels (as the mesentery of the rabbit) present an astonishing number under inflammation.

While new capillary vessels form, the old ones dilate, and assume the appearance of small arteries or veins according as they are continuous with the arteries, or border on the veins.

The fact has long been known that when coagulable lymph has been poured out, i, inflammation, blood-vessels gradually form in it, whereby it obtains a vascular connection with the surrounding textures, and becomes a living portion of the body : and these microscopic disclosures of the manner-

in which they form appear to me to possess a peculiar interest.

I should be making a very wasteful use of your time and of my own, if I entered into the undecided and unprofitable disputes that have been raised respecting the vital conditions of the vessels engaged in inflammation. While some have pretended that the action of the small vessels is increased, others assert that it is diminished ; that the vessels are in a state of atony. For my own part I have never yet seen any conclusive evidence that the small vessels possess any vital contractile power distinct from their elasticity. And granting them such a power, it is extremely difficult to conceive how any increase in their vital contraction should produce the changes that are observed in inflammation. Certainly we have no warrant that any such contraction takes place, in the results of microscopical examination of the vessels of an inflamed part. The inquiry might be more properly directed, I think, into the vital conditions of the *nerves* of the part : but here we are wholly in the dark.

I do not think it so evident as some have supposed it to be that a greater quantity of blood than is natural passes through an inflamed part in a given time. It is quite true—and it is proper that you should be aware of it—that the arterial trunks leading to an inflamed part often pulsate with more than ordinary force, and, if opened, project a jet of blood farther than they would naturally project it. It is true also that a venous trunk leading from an inflamed part will discharge a greater quantity of blood in a given time than a corresponding vein leading from a sound part. Mr. Lawrence declares that he has frequently tried this experiment, and always with similar results. He has found it necessary to bleed a patient whose hand and forearm were inflamed ; and he has opened a vein in each arm, and has found that within the same space of time, the two veins being opened at the same moment, about three times more blood flowed from the vein of the inflamed limb than from that of the sound. But it scarcely follows from this that more blood circulates through the part actually inflamed : the activity of the circulation in the vessels that remain pervious, and are merely congested, around the focus of inflammation, is greatly increased, and more blood circulates through the *limb :* and yet the blood may be stagnant, or scarcely circulate at all, in the very part that is strictly and truly inflamed. However, the fact of this increased afflux of blood towards the parts concerned in the inflammatory process is an important one.

PAROCHIAL MEDICAL RELIEF.

At the meeting of the Provincial Medical Association at Southampton, Dr. Hastings read a letter which had been addressed by Serjeant Talfourd to Mr. Rumsey, of Gloucester, in reference to the learned Sergeant's proposed bill on the subject of Poor Law Medical Relief. It was as follows:—

Sergeants' Inn, 12th July, 1840.

" My dear Sir,—I send you the clauses which, on the best consideration I have been able to give their subject, seem to me desirable, as additions to any bill which may be introduced by the Government for amending the laws for the relief of the poor. The determination of ministers, founded on the state of public business, to postpone the consideration of the bill which they had brought in to another session, has deprived me of the opportunity which, in accordance with my notice, I should have embraced, of seeking to obtain for them *this year* the sanction of the House of Commons. The great difficulties which attend the progress through the House of any bill which is not sustained by official power or urged by party zeal—difficulties which have for four years prevented me from obtaining another object, although supported by large majorities, have induced me to regard the committal of a bill conducted by Government as affording a better chance for the due consideration of the claims of the medical profession than could be obtained by attempting a substantive measure; and as the short existence proposed for the commission-continuance bill seemed to me to render a proposal for adding these clauses to that bill inadmissible, I have seen no course open to me except to defer the introduction of the clauses until next session. Perhaps the delay may be attended with some compensations, as I have thought it expedient, in framing the clauses, to depart in some particulars from the propositions contained in my letter to you of August last, and it is most desirable that the amendments to be submitted to the Legislature should first be subject to the correction of the profession, whose feelings and opinions I have only to embody in form, and humbly to represent and enforce.

" Among the slighter modifications of the plan contained in my letter of August, you will perceive that I have not attempted to define by law the limits of remuneration to medical officers, within which the discretion of the Guardians may be exerted ; but that I have been content to make it imperative on the Commissioners to issue orders from time to time, prescribing such limits, and to prohibit all attempts to obtain tenders. I have adopted this course after many and

laborious endeavours at once to lay down rules and to leave necessary discretion to the Commissioners, both as to the amount and the mode of providing remuneration, which have convinced me that the attempt must fail. Perceiving, however, that there is little difference between the Commissioners and the medical witnesses respecting the amount of compensation and the proper mode of applying it, I hope the necessity of making orders on the subject will practically ensure the adoption of a course in accordance with the moderate and just wishes of the profession.

" In providing for the qualification of medical officers, I felt it just to exempt from the requisition of surgical honours the apothecaries who may be in practice at the time of passing the Act. I have been induced to recommend this exception by communications I have received from practitioners who pursue a laborious and honourable course, with only the apothecaries' license, in remote districts, and who have expressed painful apprehensions lest the obligation to employ a surgeon should compel the introduction of strangers to share their small and ill-remunerated practice, and whose fears have been expressed in a manner I could not resist. I have also forborne to embody the proposal I once made, that the Guardians should be compelled to prefer a party who had resided a certain time within the district, to a stranger, unless on reasons approved by the Commissioners ; as I can conceive the existence of reasons justifying them in declining to engage such a resident, the statement of which might be very invidious and painful. But in this particular, as in all others, I shall be most happy to be instructed by the judgment and experience of your Committee, and, as far as possible, to meet their wishes.

" As the additions which have been made to the clauses since they were printed are chiefly intended to carry out important suggestions of your own, I need not trouble you with any explanation of their objects, but now leave you to decide how far the language I have used aptly represents your meaning, and is calculated to accomplish your purpose.

" I remain, my dear sir,

" Yours faithfully,

" T. N. TALFOURD."

PROPOSED CLAUSES.

I. *A medical commissioner to be appointed in addition to the three Poor Law Commissioners.*

And be it enacted—That it shall be lawful for her Majesty, her heirs and successors by warrant under the royal sign manual, to appoint one fit person, being a physician or surgeon lawfully qualified to practise in physic or surgery, for a period of not less than five years, to be a Commissioner to carry into execution the Acts relating to the poor

in England and Wales, in addition to the three Commissioners appointed under such Acts, and to be styled " The Medical Poor Law Commissioner for England and Wales," and also from time to time, at pleasure, to remove such Medical Commissioner ; and, upon any vacancy in the office of Medical Commissioner, to appoint some other such person to the said office ; and that the said Medical Commissioner shall be sworn, and his appointment notified in the manner prescribed in respect of the other Poor Law Commissioners; and that being so appointed and sworn, he shall attend at the meetings of the Poor Law Commissioners, but shall not have any voice at such meetings, except in matters concerning the medical relief of the sick poor, in which matters he shall have equal voice with such other Commissioners ; and all rules, orders, and regulations relating to such medical relief shall be sealed or stamped with the common seal of the Poor Law Commissioners, and shall have the same force and effect, and be received in evidence in like manner with other orders, rules, and regulations, sealed or stamped with the said seal.

II. *The Medical Commissioner to settle the extent and boundaries of medical districts throughout England and Wales within three years, and submit the scheme thereof to a Secretary of State, to be laid before Parliament.*

And be it enacted — That the Medical Commissioner, with the aid and under the authority of the other Poor Law Commissioners, shall, after the passing of this act, proceed with all convenient dispatch to take into consideration the size and population of every district for the administration of medical relief throughout England and Wales, to be committed to the charge of a medical officer in order to settle the extent and boundaries thereof upon the scheme following ; that is to say, that no district shall include a larger population than ten thousand persons.

That districts of greater area than eight thousand acres (about twelve square miles) shall not include a population of more than four thousand persons.

That districts of greater area than one thousand acres (about one and a half square mile) shall not include a population of more than six thousand persons.

That districts of area less than one thousand acres may contain a population not exceeding ten thousand persons.

And that the Medical Commissioner shall, within three years after the passing of this act, complete the regulation of all districts throughout England and Wales, and submit the scheme thereof, specifying the extent, and boundaries, and population of all such districts to one of the principal Secretaries of

State; and such scheme shall be laid before both Houses of Parliament within six weeks after the receipt of the same by such principal Secretary of State, if Parliament be then sitting; or if Parliament be not then sitting, then within six weeks after the next meeting thereof.

III. *The Medical Commissioner and Poor Law Commissioners to make orders and prescribe limits to the remuneration of medical officers, with power to suspend or vary such orders.*

And be it enacted—That the Medical Commissioner and the other Poor Law Commissioners shall from time to time make orders, whereby they shall prescribe limits within which the remuneration of medical officers may in every case be determined by the Guardians of every Union, provided always that it shall be lawful for the said Commissioners at any time to suspend or vary the operation of such orders in any particular case or cases, by writing under the hands of any two or more of them, of whom the Medical Commissioner shall be one.

IV. *Every medical officer to make an annual district report, and transmit the same to the Medical Commissioner, and the Medical Commissioner to make a general current report, to be annexed to the report of the Poor Law Commissioners, and laid with it before Parliament.*

And be it enacted — That the medical officer of every district shall, on or before the 25th day of March in every year after the passing of this Act, transmit to the Medical Commissioner a district report, stating the number of persons who shall have received medical relief during the preceding year within his district, the expenses of such relief, and the proportions and manner in which such expenses have been or will be defrayed, the distance of his own place of abode from the most remote inhabited part of his district, and if he shall not reside therein, in addition to such particulars as aforesaid, the distance of his place of abode from the nearest inhabited part of such district, and all such other matters as the Poor Law Commissioners shall by their orders from time to time require to be included in such district report.

And that the Medical Commissioner shall once in every year prepare a general report, comprising the substance of such district reports, and all proceedings of the Poor Law Commissioners relating to medical relief in such year, and cause such general report to be annexed to the annual report of the Poor Law Commissioners, in order that the same may be submitted therewith to one of the principal Secretaries of State, and laid therewith before both Houses of Parliament.

V. *Guardians to determine the amount of remuneration to be received by medical officers, subject to the orders of the Commissioners, but not to advertise for or seek to obtain tenders.*

And be it enacted—That the remuneration to be received by medical officers shall in all cases be fixed and determined by the guardians of the poor of every Union, according to their discretion, subject to any limitations and directions which may be contained in the orders of the Commissioners, and that such guardians shall not attempt, by advertisement or other public notification, or in any manner whatsoever, to obtain tenders or offers relating to the remuneration to be given for the performance of the duties of such medical officers.

VI. *Qualification of medical officers.*

And be it enacted—That no person shall hereafter be eligible to receive the appointment of medical officer of any district not being duly qualified to practise as a surgeon and physician, or as a surgeon and apothecary, unless he shall be in actual practice as a surgeon or apothecary at the time of passing this act; and that no person shall be so eligible until he shall have been in surgical or medical practice for three years.

VII. *The expense of medical relief to be a parochial charge.*

And be it enacted—That in all cases the expenses of medicines and administering medical relief shall be borne by the respective parishes in or of every Union, in proportion to the expense incurred on behalf of the parishioners of each parish who shall receive such relief.

ON THE

STRUCTURE OF NORMAL AND ADVENTITIOUS BONE.

To the Editor of the Medical Gazette.

Sir,

The inclosed paper contains the result of observations on the structure of bone, made at various times during the last three years. It was read before the Royal Society last winter, and I have now added here and there new matter from my physiological note-book.

I remain, sir,

Your obedient servant,

ALFRED SMEE,

Surgeon to the Bank of England, and to the Provident Clerks' Mutual Benefit Association.

Bank of England, Oct. 27th, 1840.

The intimate or microscopic structure of bone has been the subject of much

investigation both in this country and abroad, yet there still appears to be much scope for farther discoveries. To the uninitiated the structure of bone under the microscope is one of the most splendid sights possible.   To the initiated, though he may often have participated in the pleasure of examining, it yet the beautiful arrangement never ceases to afford the greatest delight.

The best mode of preparing the sections of bone is to cut portions, of a convenient thickness, with a saw, and then to rub one surface quite smooth on a hone, and afterwards to polish it upon a piece of leather; a slip of glass is then to be obtained, and one or two drops of balsam of Canada are to be placed on one surface: the polished side of the bone is to be put on the balsam, the glass is to be heated, which melts the balsam, and causes it, when cool, to fix the section firmly on the glass.   The next operation is to polish the opposite side of the bone, and render it sufficiently thin to be translucent, which is to be effected either by grinding it upon a hone, or, if the section is very thick in the first instance, by filing the bone down to the required thinness; lastly, the specimen is to be polished as before.   Occasionally the structure is best seen by scraping down the bone, but this is a tedious operation, and seldom required.

The sections by these processes are made extremely thin, and are now fit for examination by the microscope. The canals of Havers are seen conspicuously when the bone is moderately magnified.   They are irregular canals running for the most part in the direction of the long axis of the bone, and frequently anastomosing with each other.   They are frequently seen to arise either from the external or internal margin of the bone.

Around these canals are small irregular bodies, arranged in circles, and having the surfaces parallel to the long diameter, looking towards their several canals.   Apart from these series of corpuscules, attached to the Haversian canals is a row running round both the exterior edge of the bone and the edge of the medullary cavity.   These run round every filament of the cellular tissue of bone, which, unless any portion happens to be very thick, has more of the Haversian canals.

A junction is effected between the corpuscules and the Haversian canals, and also between corpuscules and the margins of the bone, by numerous little fine lines which communicate in every direction with the neighbouring corpuscules. These fine lines also connect the corpuscules of the extreme circles round each Haversian canal with the corresponding corpuscules of the neighbouring canal.   Between the system of corpuscules surrounding the Haversian canal there is no row taking the general direction of the bone, as some have asserted.

If the Haversian canals are examined in a recent subject, where the capillaries are well filled with blood, they are observed to contain vascular tubes, and the blood can be distinctly recognised in them.   To ascertain this fact it is better that the bone be scraped, and no heat applied to fix the bone to the glass.

The corpuscules are arranged around the Haversian canals in a series of rows proportionate to the size of the canals: thus a small canal has one, two, or three rows round it, while a large canal has five or six rows.   It is to be noticed that the rows around the medullary canal and external edge of the bone seldom exceed two or three series.

An opinion is very prevalent amongst physiologists that these little bodies are solid; and many consider that they consist of the phosphate of lime and earthy matter of bone; but this opinion appears to be incorrect, from viewing sections of bone under different circumstances.

A similar opinion has been entertained of the fine lines running from the corpuscules, which have been termed the calcigerous tubes, but I would suggest the name of corpuscular lines or tubes, as the truth of this will be shown presently.

When a section of fresh bone is examined, these bodies appear opaque as well as their lines; but when a section from the same bone is thoroughly boiled in balsam of Canada, the balsam enters the canals of Havers, the corpuscular lines disappear, with few exceptions, and some of the corpuscules become transparent and nearly invisible, and others partially transparent.   The same effect has been produced by our forefathers in their process of em-

balming; for in the tibia of a mummy, which I possess, the corpuscules are transparent, and most of them are decidedly filled with a yellow matter similar to that which exists in the blood-vessels. The corpuscular lines are so translucent as to be scarcely visible. In this case the canals of Havers were also filled with yellow matter.

When the section of recent bone is ground down to the utmost possible limit, the corpuscules either appear as a transparent irregular oval ring, or they have the appearance of containing some shrivelled matter in their interior. In these cases the section of bone is only a portion of corpuscule in thickness.

The corpuscules with the lines are exceedingly opaque when a section of bone is examined in which the canals of Havers are filled apparently with adipocire, which occasionally happens after maceration.

If a thin section of bone is thoroughly calcined, then soaked in oil, and afterwards carefully ground down extremely thin, the canals of Havers, the corpuscules, and corpuscular canals, will be quite visible in the substance of the bone.*

When the earthy matter is removed from calcined bone, the corpuscular lines disappear, but the corpuscules themselves, though transparent, are still visible.

In these instances the examination has been made by transmitted light; but differences, according to circumstances, are seen when the object is viewed by light thrown on the surface. The corpuscules with the lines appear white when a thin section is examined with a dark ground underneath it; but a thick polished piece of bone, or a section of bone with a portion of white paper underneath it, does not present these appearances. The reflection of light from the deeper corpuscules is the reason why the corpuscules are not apparent in a thick section, nor when white paper is placed underneath one of greater tenuity. Those corpuscules which present a transparent ring by transmitted

light still appear white when viewed by reflected light, for some are seen as white rings on a black ground, and others as rings having a little irregular white matter in the centre. The whiteness of the corpuscules is owing to the reflection of light from the surface of the corpuscules, whilst between them it passes to the back, and is absorbed. The same effect is produced when a piece of black cloth or scratched glass is viewed under similar circumstances, in which cases the elevations on the one and the depressions in the other appear white.

If, however, the piece of mummy bone before mentioned be examined by reflected light, the transparency of the corpuscules allows the light, in some degree, to pass, and that part which is reflected appears of the same yellow colour as when the section is viewed by transmitted light.

Such are the principal circumstances which modify the appearances of the corpuscules, and which may be thus summed up : first, that the earthy matter is associated with the animal matter, and pervades every part of the bone, which is shown in the section of burnt bone ; secondly, that the corpuscules may exist without any earthy matter being there, as in the cartilage of the shark, or the animal matter of bone which is left after maceration ; thirdly, that the corpuscular canals communicate with the Haversian canal, as the specimens boiled in Canada balsam prove ; fourthly, that the corpuscules present themselves under two circumstances, for they are either opaque, as in recent and adipocire bone, or transparent, as in those boiled in balsam of Canada, as are also those of the mummy bones.

All these facts shew that the corpuscules and corpuscular lines are themselves cavities into which the various substances enter. We have already mentioned that, in the bones of mummies, a yellow matter is found in the corpuscules similar in appearance to that filling up the Haversian canals. That they are cavities is farther proved by the corpuscules appearing as rings when the section is reduced to extreme tenuity.

Attempts were made to fill the cavities with a coloured substance by various methods, such as had been effected in the bones of the mummy,

* The labour and care required to make these specimens are very great. It is better to calcine a thin section in a crucible, over a hot fire, then to place it in oil, and keep it there for a very long period, when it may be fixed to the glass with balsam of Canada. No heat should be applied, but it must be allowed to remain till it spontaneously dries, when its thickness may be further reduced and gently polished.

but watery solutions penetrated only for a short distance into the Haversian canals, so that double decomposition of ferrocyanate of potass and sulphate of iron were found to be useless.

Balsam of Canada and dragon's blood were melted together, and pieces of bone were then boiled in the mixture. On the examination of thin sections of this, the Haversian canals were found filled with the compound, but whether it entered farther I could not so satisfactorily make up my mind as to enable me to state the fact positively, but, upon the whole, after numerous examinations of various specimens prepared in this manner, it may be stated that there was an appearance in those corpuscules, immediately surrounding the canals, of its having penetrated the cavities ; but, perhaps, the facts already adduced require no confirmation.

Having proved by the results of direct observation that the corpuscules are cells, and, therefore, ill named corpuscules, but better cellules, their use is the next point which demands our notice ; but this will probably be for ever theoretical. Perhaps they act the same part to compact tissue of the bones as cells do to the cellular, namely, that of giving lightness without materially diminishing their strength.

What the particular structure of the bone is between the corpuscular lines and corpuscules there appears to be no means of ascertaining ; for the highest power in the thinnest section only exhibits a transparent homogeneous texture.

Whether the corpuscular tubes contain blood perhaps we may also for ever be ignorant, but, considering that they communicate with decided bloodvessels, this opinion is far from improbable. It is certain they are much too small to carry the globules, but the opinion of their being blood-vessels may receive additional weight from the fact that in bone there are no canals smaller than the Haversian.

The size of the corpuscules or cellules is about equal to two or three globules of blood ; they appear for the most part broader when viewed in a section parallel to the Haversian canals, than when seen in a section perpendicular to them : if it is really the depth which is seen in the longitudinal section of bone, it follows that these little bodies

are deeper than they are broad, and we have already noticed that their length is much greater than their breadth. I conceive that the form of the corpuscules may be exactly given by taking a piece of wood twice as deep as it is broad, and twice or three times as long as it is deep, and then rounding off all its angles. Sections in different planes through this would present every form which is observed in the corpuscules.

Thus we have seen that the structure of bone is extremely simplified, as there is a medullary cavity, from which spring the corpuscular tubes, and three or four layers of corpuscules or cellules around it. The same is seen with regard to the exterior part of the bone. Between these two layers run tubes for blood, irregular as to size, frequently anastomosing with their neighbours, and having the general direction of the bony tissue in which they are imbedded.

Radiatory lines are spoken of by some as existing round the Haversian canals, but they have no real existence, and are only the corpuscular canals or lines seen deep in the section, and out of focus ; and they are only to be seen when these lines are opaque, and the section thick.

The cellular tissue of bone has no Haversian canals ; for there the cells have the same relation to the bony structure of each cell as the Haversian canal has to the bone immediately surrounding it.

With regard to the laminæ of bone which have been described by other authors, they appear to me to exist only as the result of the ingenuity of the anatomist, for we see that the shaft of a long bone consists of a large medullary cavity, with a series of corpuscules and corpuscular lines, and a number of Haversian canals containing blood, with their series of corpuscules around them. Now if a bone has long undergone putrefaction, it can be torn precisely in this manner. It will, in fact, tear to shreds, and a transverse section of each of these shreds shows the Haversian canal in the centre, and the corpuscules around it.

The corpuscules are to be seen in every true bone of the body, and form a good criterion to distinguish bone from other tissues. It is worthy of remark that but little difference exists between the structure of different bones, and even the intense hardness of the tem-

poral bone immediately surrounding the semicircular canals presents no microscopic difference to account for that peculiarity.

The changes which bones undergo in the interior of the earth are very interesting. They may have their animal matter entire; they may have the animal matter removed; they may have the earthy matter partly removed; or, lastly, the animal matter may be earbonized.

The bones which exhibit the animal matter entire are those which have lain in certain situations not exposed to the air. I find them in this state from Beg Bone Lick, in Kentucky; and I have sections of the bones of the mastodon from thence, shewing the structure in the most beautiful manner. Some bones found in making a sewer behind the Bank of England, together with Roman sacrificial utensils, were in a similar state. In both these instances, as well as in others, the Haversian canals appeared to be full of black matter.

The relation which the proportion of animal matter bears to the earthy, I have examined by calcination in twenty different species. The bones were all well macerated, and not greasy. The proportion in these varies but little one way or another, and that more from the state of the bone than any thing else; for the average is as near as possible sixty per cent. of earthy material.

When the animal matter is removed we may always venture an opinion that the bone has been imbedded in a sandy or gravelly stratum. In every churchyard with this soil, that I have examined, bones have been found with the smallest trace of animal matter, and others not so far advanced in decomposition have been noticed. Many fossil bones possess their phosphate of lime, with so little animal matter as scarcely to be coloured by heat. None of the bones without animal matter can by any contrivance whatever be made to show the corpuscular structure, although the Haversian canals are distinct to the naked eye, and the general appearance of the bone is not materially altered, except perhaps being white, and of a somewhat mineral aspect.

The next division is that in which the animal matter is too abundant, part of the earthy matter having been re-moved. This condition is rare, and in these cases the bone will tear into shreds, each containing its Haversian canal and series of corpuscles. I do not know under what conditions this takes place.

The last change is the conversion of animal matter into bitumen or carbon. This change is common to the blue clay and blue lias, as here the bones retain their usual quantity of phosphate of lime, but their animal matter is converted into coal. This alteration appears quite unconnected with heat, and takes place as a spontaneous change in a moist situation, to which no air has access. I have seen different bones in every transition of this change from different situations; they mostly show not only the Haversian canals but even the corpuscles.

We have next to examine adventitious bone, which may be arranged under the heads—reproduction of bone, growths from bone, and ossifications of other tissues. Of the former a piece of callus from a simple fracture was examined, and was not found to differ in any respect from true bone; it had the cellules with their lines, and the Haversian canals, precisely as normal bone. The same thing was noticed in a section of callus from a compound fracture. The new bone after necrosis, or even the necrosed portion, exhibited no diversity from this structure. The reproduction of bone is particularly interesting, as the new deposit is precisely the same as normal bone, with almost all the tissues : the reproduced part widely differs from the normal tissue.

Of the different growths from bone, a piece was examined which had been thrown out from two anchylosed vertebræ for additional strength, and this presented the appearance of true bone.

Hard bony exostoses were examined with exactly the same result.

Ossifications may be divided into two classes—bone of cartilages, and bone of other tissues. Ossifications of the thyroid and corocoid cartilage in the human subject were examined, and both presented the cellules, and the former the Haversian canals not at all different from recent bones.

The human trachea is not in general sufficiently ossified to show the corpuscles of the natural size, for in partial ossifications large cells are seen, but a section of a small part showed these cel-

lules of the size natural to bone. The trachea of the macaw, and the inferior larynx of the widgeon, which are naturally bones, also present no difference from the general appearance of bone.

Examinations of the structures of the costal cartilages when ossified were attended with like results.

The ossification in the thyroid ligament was examined, which showed here and there the cellules.

The fibrous membranes when ossified do not generally exhibit this structure: in fact, we may say never, unless they be connected with bone. A portion of ossified tendon attached to bone was examined, which had these cellules differing in no respect from bone.

A section of a fibrous tumor of the uterus was examined. This had the fibres running in the osseous matter, but no cellules nor anything like cellules could be discovered.

Of the serous membranes, the pleura is sometimes ossified, but that appears to be only a deposit of irregular granules, and no structure could be detected.

The arterial tissue is frequently ossified, and then its appearance is similar to that of the pleura; it displays a granular mass and no cellules.

Thus we may state that ossifications are of two kinds: first, that of true bone, which, in a word, always exists when any enlargement of bone in any way takes place, either as an ossification of the neighbouring tissues, or in any other way. Secondly, ossification of the tissues not at all related to bone, which presents nothing but a mass of granules.

The structure of bone from a very old person was examined, which, after six weeks, had made no effort at reparation, but no difference could be detected.

A section of a femur was examined, in which the head of the bone was affected by scrofula, but no change could be detected in the cellules.

A transverse section of enlarged femur had the cellules in the enlarged part, but in this case the canals of Havers did not run in the direction of the long axis of the bone, but ran from the exterior edge.

The structure of bone and that of the cellules have been examined in numerous specimens of recent bone from different parts of the body. The long, the round, the flat, the sesamoid bones, have all received their share of attention, and these, with macerated bones, mummies' bones, bones altered by chemical agents, diseased bones, and ossifications connected with cartilage or bone, possess these cellules.

The bones of animals and of birds which have been examined also possess them. The bones of some fish, as the sturgeon and porpoise, and the ossific plates or the skin on the former, agree in possessing these cellules. Even the cartilaginous fishes are not destitute of them.

The structure of bone is not only such at the present moment, but has been the same from earliest period, for the mighty ichthyosaurus, the tyrant of the water in former ages, and the vast mastodon, the giant of the land, possessed these cellules. Although six thousand years had elapsed before the microscopic structure of bone was made known to the anatomist, yet in every age, in every country, geological and antiquarian researches have revealed that the same structure has existed. The imperfection of our instruments has been the cause of our previous ignorance, and doubtless there is now ten times more to be learned than is already known.

In every case where the corpuscules or cellules exist, they can be distinctly perceived to be hollow. Let, therefore, the universality of this fact be the only apology for its communication.

For the following measurements I am indebted to the kindness of Mr. Bowerbank:—

Haversian canals.

Small.   Large.
$\dfrac{1}{303}$ $\dfrac{1}{500}$ in diameter.

Corpuscules or cellules seen in a transverse section.

One of the largest.

Diameter $\dfrac{1}{4098}$ Length $\dfrac{1}{1445}$

One of the smallest.

Diameter $\dfrac{1}{9346}$ Length $\dfrac{1}{2353}$

Longitudinal section.

One of the largest.

Diameter $\dfrac{1}{2024}$ Length $\dfrac{1}{727}$

One of the smallest.

Diameter $\dfrac{1}{4166}$ Length $\dfrac{1}{837}$

STATISTICS OF SMALL-POX.

To the Editor of the Medical Gazette.

SIR,

THE second report of the Registrar-General contains a letter from Mr. Farr, which, besides other interesting matter, details the principal results of the great variolous epidemic which pervaded England and Wales in the years 1837, 1838, 1839, having its climax about the month of May 1838. To these statistical details, arranged in a manner the most complete that can be desired, and presenting indeed the beau ideal of statistical perfection, Mr. Farr appends some very instructive suggestions regarding the causes of epidemic prevalence, and the laws which appear to regulate the phenomena of epidemic culmination and decline. I should have been gratified by finding such valuable matter transferred bodily to your columns; but as you may have been deterred from this by the minuteness of many of the details, and the length to which the observations extend, I have thought that a short notice of the principal facts, drawn up rather with a view to popular instruction than to satisfy the cravings of a professional statist, might not be unacceptable to your readers.

The recorded facts extend from the 1st of July, 1837, to the 31st of Dec. 1839. These two and a half years are subdivided into ten quarterly periods. One table (table P), occupying sixteen octavo pages, exhibits the total amount of deaths by small-pox occurring during this long period, in each of the 324 divisions into which England and Wales are divided for the purposes of the Registration Act. The general results may be conveniently summed up in the following words:—

There died in the summer quarter of 1837 by small-pox throughout England and Wales 2513 persons. In the last quarter 3289. Total in the last six months of 1837, 5802.

There died of small-pox throughout England and Wales—

In the first quarter of 1838,			4242
In the second do.	.	.	.	4489
In the third do.	.	.	.	3685
In the fourth do.	.	.	.	3851

Total . . 16,267

There died of small-pox in like manner

In the first quarter of 1839,	2982
In the second do.	.	.	.	2505
In the third do.	.	.	.	1533
In the fourth do.	.	.	.	1730

Total . . . 8750

Total deaths in the two and a half years, 30,819, giving for this period an average of 12,200 deaths per annum. As the rate of mortality during these three years has ruled about 20 (or from that to 25) per cent., it follows that in the course of one epidemic, extending through thirty months (that is, between the 1st of July, 1837, and the 31st of December, 1839), there occurred in England and Wales not less than one hundred and fifty-four thousand cases of small-pox. This statement is certainly rather startling, and shews how greatly some of our predecessors had over estimated the probable results of the Jennerian discovery.

From the preceding facts it will be seen, that the epidemic reached its maximum of intensity in the spring quarter 1838, and that its decline exhibited irregularities; the fourth quarter of both 1838 and 1839 shewing a slight increase over the preceding quarter. The epidemic commenced in the western shore of the island: Liverpool, Bath, and Exeter, being the towns that chiefly suffered in 1837. The metropolis and the southern counties were the chief seats of the epidemic in the early part of 1838. At Manchester and Leeds the epidemic was at its height in the last quarter of 1838; the former town returning 180, and the latter 197 deaths between the 1st of October and 31st of December, 1838.

In the early part of 1839, the eastern portions of the kingdom experienced their share of the malady. Norwich returned 384 deaths in the first half year of 1839. The disease having made a sweep round the island seems to have returned again to its first haunts, for at Liverpool 138 deaths occurred in the last quarter of 1839; at Salford 80, and Bradford 80. The total deaths in Lancashire mounted up to 446 during the same period, having in the spring (or second) quarter been returned at 179 only.

Your readers may perhaps be interested by some more minute details with reference to this epidemic, as it occurred in the metropolis. It will be

borne in mind that the metropolitan Districts, in the Registrar-General's books, extend over an area of 70 square miles, and were estimated to contain in 1838, 1,884,844 inhabitants. The deaths by small-pox in the metropolis in the period comprised in the returns may be exhibited in the following table :—

Table shewing the deaths by small-pox in London between the 1st of July, 1837, and the 31st of December 1839.

Metropolis.	Deaths by small-pox in each quarter.	Deaths in each year.
Third quarter of 1837	257	763
Fourth do. . . .	506	
First quarter of 1838	753	
Second do. . . .	1145	
Third do. . . .	1061	3817
Fourth do. . . .	858	
First quarter of 1839	364	
Second do. . . .	117	
Third do. . . .	65	606
Fourth do. . . .	60	
Total	5186	5186

The mortality from small-pox, according to Mr. Farr, was greater in the metropolis, with reference to its population, than in all the other parts of England. The district that most nearly approaches the population of the metropolis (somewhat exceeding it) is the District No. 8, comprising Cheshire and Lancashire. In this district the deaths by small-pox were

In 1837 . . . 1191
In 1838 . . . 1907
In 1839 . . . 1993

Total 5091

The advantage, it will be seen, is in favour of the country, but the difference is not great. Indeed, considering the difficulty of estimating accurately the population seven years after a census, these numbers shew a very remarkable coincidence in the extent and ravages of the disease, under circumstances apparently so different as are those of the metropolis and the great manufacturing district of England.

The next circumstance that claims attention is the age at which the mortality occurred. Mr. Farr does not profess to give full particulars on this head, but he states in his second letter the ages of 8706 persons who died of

small-pox in 1839, and his first letter specifies the ages at which 1,056 persons died in 1837. The results of the two sets of observations may be summed up in the following table :—

Table of the ages of 9762 persons who died of small-pox in England during the years 1837 and 1839.

	Deaths.
Under the age of five years . .	7340
Between the ages of 5 and 15 .	1668
—————————15 and 30 .	528
—————————30 and 70 .	210
Upwards of 70 years of age .	16
Total .	9762

From this table we learn, that the great majority of deaths by small-pox occurred among infants and very young children, not one of whom had probably ever been vaccinated. This shews how greatly vaccination is neglected throughout England, and how urgent was the necessity for some legislative enactment for the extension of vaccination. Whether the Bill of last session was the right measure is quite a different question, on which I shall hope, ere long, to be permitted to offer some observations in your columns. The fact, that out of 9762 persons dying of small-pox, 754 only were *adults*, is very striking. Whether the same proportion held good in epidemic visitations, prior to the discovery of vaccination, is a point which, I fear, we have no means of ascertaining. I suspect, however, that in all periods of the world, the ages from birth to five years have been those on which the ravages of small-pox have chiefly fallen.

Hitherto the registrar's returns afford no clue by which we may determine that very interesting question, what proportion of the deaths by small-pox, throughout England, have taken place among the vaccinated. We have satisfactory evidence that, under fifteen years of age, the deaths by small-pox after vaccination are scarcely noticeable ; so that the proportion must necessarily be very small, seeing that only one-thirteenth part of the total mortality is open to such a contingency. To determine the exact proportion, however, be it large or small, is an important object, and measures are now in progress to meet this desideratum. A recent order from the Registrar-General, addressed to the

registrars of the metropolitan districts, directs that the fact of previous vaccination shall hereafter be inquired into and registered in all cases, so that in a few years, and especially when the order is extended to the whole of England, we may be assured of arriving at great certainty in this department of pathology.

The questions mooted by Mr. Farr, with regard to the laws which regulate the origin, culmination, and decline of variolous epidemics, must, with your permission, be reserved for a separate communication.—I am, sir,

Your obedient servant,
GEORGE GREGORY.

31, Weymouth Street, Nov. 16, 1840.

CASE OF HYDROCEPHALUS CURED.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH there is nothing novel in the history or treatment of the following case, I conceive that the publication of it may be useful. It may stimulate medical men to continue to use their best endeavours in cases apparently hopeless. Near relatives, from fear of giving unnecessary pain to the patient, and nurses, in order to save themselves trouble, often discourage the use of means in cases apparently much less hopeless than the one which I have described.

Qui nil potest operare, desperet nihil.

Was the serous effusion on the brain in this instance superficial, not extending to the ventricles?

If you deem this case worth notice, please to give it a place in the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,
CALEB CROWTHER, M.D.

Wakefield, Nov. 17, 1840.

Master Alfred Beckett, aged 11 years and a half, of leucophlegmatic habit, was attacked with scarlatina on the 1st of September, 1840. The fever continued in a mild form for about a week. He remained very feeble and languid until the 28th, when he became œdematous. He was seized with sickness and vomiting on the 4th of October, which continued until the 7th.

On Monday evening, the 5th, at six o'clock, he was seized with convulsions, which continued until six o'clock the following morning. He became blind on the 5th, and continued to be so until the 8th, the pupils continuing immoveable. His sense of hearing was very acute. He laboured under severe dyspnœa, constant cough, and jactitation of the limbs, from the time he became convulsed until Wednesday the 7th, when he, for the first time, slept for a quarter of an hour, since the attack of convulsions. He began to complain of his head, accompanied with a sense of heat, on Monday morning, the 5th.

I saw him for the first time on Monday evening, about half-past 8 o'clock, when the pupils were dilated, the tunica albuginea pale, the pulse quick, feeble, and hurried; the tongue furred and dry, the bowels confined, the urine scanty, the face œdematous. He was delirious, and continued to be so until the 7th.

In the absence of Mr. Bennett, I attended this case, with Mr. Ross, for the first two days, and afterwards with Mr. Bennett. My prognosis was in the highest degree unfavourable. I recommended his parents, however, to persist in the use of means, stating that now and then, once perhaps in a thousand times, a patient under similar circumstances recovered. I ordered a blister to be applied to the shaved head, the black purgative mixture to be taken frequently, until it operated; pil. hydrarg. gr. ij. to be taken every two hours, with a dose of a diuretic mixture consisting of liq. ammon., acet. tinct. scillæ, and tinct. digitalis. He had no motion until the 7th in the morning, when he was freely purged, the stools being dark and very offensive. He voided very little urine until this time, when so copious a diuresis supervened that he was almost constantly wanting to void urine, and often wetted his bed. He began now to sleep soundly and frequently.

On the 8th the delirium left him. He still continued to be purged. The œdema had very much diminished. On Wednesday morning, the 7th, the extremities became very cold, and the pulse scarcely perceptible; he appeared to be dying. Towards evening, however, he rallied, and from that time continued gradually to recover. His

cough continued to be troublesome for several days. Since he became sensible he has had no pain in his head; his appetite has returned, and he was disposed to take more food than was proper for him: he did, indeed, one day suffer some inconvenience from taking too much pudding. His purging continued until the 11th, when his motions became natural in colour and in consistence. On the 14th the œdema was gone; he continued to void urine freely, taking one dose of his diuretic mixture daily.

November 5th.—He is now very well again.

OBSTRUCTIONS IN THE EAR.

To the Editor of the Medical Gazette.

SIR,

THE few desultory remarks which follow are extracted from my note-book. If you think they are sufficiently interesting for insertion in your truly useful hebdomadal, they are much at your service. —I have the honour to be, sir,

Your obedient servant,
and constant reader,
CHARLES THORNHILL.

Darlaston, Staffordshire,
Nov. 2, 1840.

Extraneous substances in the auditory passage are highly injurious to the function of hearing, from their tendency to destroy the connection which subsists between the internal ear and the propagation of sound. In proportion to their size, these substances more or less shut out the sonorous rays, and prevent their duly acting upon the delicate membrane of the tympanum; but, although they operate for the time as causes of deafness, the sense of hearing is fully restored as soon as their removal is accurately accomplished. This is *generally* remarked to be the case; but there is no rule without an exception, as will be shewn even on this subject.

Many persons, accustomed to ear-ache, are in the habit of employing lint, cotton, or paper, for the purpose of filling up the external meatus; and this is done in order, as they tell us, to secure the good effects that may result from pressure on its lining membrane. This is quite an erroneous notion; for, so far from effecting good, positive harm is the frequent result of the practice. In illustration of this remark, I may mention an instance that occurred under my own observation.

Whilst syringing the ear of an elderly patient, who had long been the subject of deafness, after having removed a considerable quantity of hardened cerumen, a piece of paper was extracted closely coiled together. This was positively affirmed to have remained in the passage for no less a period than *twenty years*, the individual having a perfect recollection of the occasion on which it was placed there. On continuing the use of the syringe after this was removed, the water was readily propelled through the ear into the cavity of the mouth, by means of the eustachian tube, at each stroke of the piston. No doubt, from the close and constant contact of the foreign body for so long a period, the membrana tympani became so materially injured as ultimately to be destroyed; and this would account for the facility of communication between the ear and the mouth.

There is another practice prevalent among the lower orders which is equally reprehensible; and although the effects that supervene are widely different from that before mentioned, yet they sometimes occasion the greatest inconvenience. When troubled with an accumulation of wax in the ear, it is not uncommon for them to attempt removing the same by boring with pins and other sharp-pointed instruments, and this frequently produces such irritation in the lining membrane as to give rise to diseased action, and eventually create morbid deposit.

A case of partial deafness from this cause fell under my notice some short time ago. George G——, ætat. 19, called one morning to consult me respecting a difficulty of hearing, with which he had been afflicted for the space of two years. About the period of its first occurrence he had been in the frequent habit of using pins to scoop out the hardened secretion from the ear; but the custom had been desisted from latterly, on account of its being sometimes followed by an oozing of blood. On examination, I found that the passage was completely obstructed by a soft fleshy polypus, which could be drawn forward without difficulty. After representing to him the nature of the case, he immediately consented to its removal.

Having taken firm hold of the substance by the aid of a pair of short forceps, I commenced making gentle extension, when, after having performed three or four twists, it gradually but speedily gave way at its base. Slight hæmorrhage ensued, which continued for some time. To restrain the bleeding, I touched the parts with a little of the tinctura ferri muriatis, and afterwards gave directions that an acidulated lotion should be injected twice a day into the external meatus. The substance removed was about the size of a common horse-bean; and upon its withdrawal the patient expressed himself as entirely relieved: indeed, to use his own expression, " he could now hear as well as he had ever heard in his life." A few days subsequently he called to say that he felt his ear was perfectly well, and that his hearing was as acute as immediately after the removal of the polypus. He also remarked, that he should not readily be induced to pick his ears as on former occasions, as all the annoyance he had experienced from the dulness of hearing was attributable to this cause.

MEDICAL GAZETTE.

Friday, November 20, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE RIGHTS AND WRONGS OF DRUGGISTS.

A PAMPHLET has just been published in the form of a Letter to Mr. Warburton*. It is written with much honesty and energy, and with some common sense; but the former qualities are generally predominant. It contains, however, many facts—confessions, we had almost said, but that we have every reason to believe that the author is no participator in the iniquities of which he is cognizant—respecting the innumerable frauds that

* A Letter to H. Warburton, Esq. M.P. on the Utility of extending the Provision of his (Medical Reform) Bill to Chemists and Druggists, and on the necessity of extinguishing Quackery by Act of Parliament. By a Druggist.

are practised by adulteration and other like means in every department of the drug trade. We did not need these to call our attention to the subject. We should ill discharge our duties as medical journalists, if we were not ever awake to subjects of such high professional importance; but a notice of the pamphlet may be of use in exciting the whole body of our profession to the inquiry, whether the evils it reveals, and of which they are among the chief victims, do not admit of some immediate and certain remedy.

The chief grievance, under which it appears from the pamphlet that the honest druggist labours, is, that there is scarcely an article of his commerce which is not, for the purpose of lowering its price, adulterated over and over again by his fraudulent competitors. Foreign drugs are adulterated abroad: the drug-merchant writes to his correspondent for a certain article, and limits him to a price which is frequently below, and often only half, that at which the genuine drug can be procured. As the price will not meet the quality, the quality, which is more easily alterable, must be brought to meet the price, and no sooner is the destination of a drug determined, than its adulteration begins; hence, senna, scammony, opium, aloes, and sarsaparilla, though really as " genuine as imported," commonly contain from five-and-twenty to fifty per cent. or more of some useless material—chalk, stones, resin, or anything that will preserve appearances. It has not long arrived before the consignee again reduces its real, with a scrupulous regard to maintaining its nominal—value, by further adulterating it, and usually (for it is there the iniquity can be most easily carried on), at the drug-mill. Returned thence, it passes into the hands of the retail druggists; thence it seldom passes even so pure as it arrived; and it arrives at last in the

stomach of the unhappy consumer, with scarcely one quality of that which it pretends to be. Happy is it for him if that which it should have been is replaced by that which is inert.

We surely need not do more than repeat, on the authority of this pamphlet, that which has already been implied or openly stated by all the first authorities who have inquired into the subject, that " adulteration is almost the life-blood of the trade of drug-selling ;" that " there is scarcely a chemical preparation in common sale or use, but what is liable to and suffers adulteration, or is brought into the market in an impure state ;" and that this " system of fraud and injury has woven itself into the habits and the very existence of those engaged in the trade of drug-selling :" and add that these statements are not mere loose assertions, but are fairly deduced results from years of close and interested observation,—we need surely not do more than this, to awaken the profession to a sense of the difficulty or impossibility of conducting a successful practice when they have only the rotten and useless materials of the average of the drug-market to depend on for remedies of disease.

It must be, and of course is, admitted, that a few of the most respectable houses may, as far as their judgment goes, be relied on for the quality of their drugs, but these constitute but a small portion, and they are themselves liable to deception by their correspondents abroad, from whom the public have no warrant whatever, and whose frauds can be detected only by the sagacity and honesty of the few honest wholesale dealers here. In the present state of things, therefore, few practitioners can feel any confidence that the medicines which they prescribe are ever really administered : it is fortunate if, in their stead, nothing mischievous is given ; but in many cases there is no doubt that medicines are adulterated and made cheap by the mixture of poisons—as of arsenic with antimony, corrosive sublimate with calomel, and so on.

What, then, are the means by which these evils may be remedied ?   by which a practitioner may be freed from the doubt which he must often entertain, whether that which he is prescribing will be curative, destructive, or inert. " Honesty and fair-dealing," no doubt, might effect it; nay, they alone can effect it, for in a case of this kind the most stringent laws are never availing beyond a comparatively small extent. But, then, they must be universal, instead of being exceptional among the members of the trade ; among whom, as among those of all other callings, there will always be plenty who will think money not dearly earned by the twinges that their consciences give them at the beginning of their nefarious practices, and who will not want cunning to evade the penalties of the laws, which they have not the honesty to obey.

The plan which the author of the pamphlet proposes would begin at the importation of the drugs : he would have inspecting officers at the docks and bonded warehouses, to inspect every article landed ; to seal those that proved satisfactory, and to re-export or destroy those that were unfit for sale. Thus, they would at least pass to the wholesale druggist pure.   The next step would be to provide against the frauds and adulterations which are in his power ; both here therefore, and in the next stages of their progress, in the shops of the retail-dealer, the author would have a complete and efficient system of inspection : no article should be allowed to pass to the retail houses till its purity were determined by analysis or inspection ; and in these

houses an eye should still be occasion-
ally cast on it before it passed to the
hands of the public.

In short, a more rigid system of in-
spection is the chief remedy proposed
by the author. We do not doubt that
it might be made of much benefit, but
as for putting an end to all adultera-
tions of drugs, no scheme of the kind
can accomplish such a result. Look,
for example, at the efforts of the
Excise Office; and, by the way, if this
plan of inspection is to be carried
out, it is there that the right and
power should be placed: look, we
say, at the Excise Office. Why, with
all the energy, and with all the undis-
puted rigid and irresistible force that
the Excise can employ, it is notorious
that excisable articles are adulterated
by dishonest men at every stage of their
progress, before they arrive at being
consumed by the public : and yet how
few are the convictions ! In this great
metropolis, in the matter of beer alone,
the number of annual convictions is
probably less than that of the honest
publicans who do not by drugs or
delusion adulterate the articles they
sell. At the same time it cannot be
doubted that, as far as it goes, the sur-
veillance of an Excise officer exercises
a most useful restraint on fraud, and it
is much to be desired that something of
the kind were established in the drug-
trade.

With reference to the parties by
whom the inspection should be carried
on, the author speaks against the Apo-
thecaries' Company with all the partia-
lity and acrimony of an opponent in
trade. It might perhaps be advanta-
geous that the licensing and the trading
part of the establishment should be
more divided, and that the right of
searching and inspecting of drugs should
be given to others than those who are
themselves of necessity either the op-
ponents or friends in business of all
those over whom they do, or if they

please may, exercise surveillance. But
the first of these questions it is no part
of the business of druggists to inquire
into; and when the writer goes out of
his way to propose the total annihila-
tion of the Apothecaries' Company, he
forgets the truth that he told in the
beginning of his pamphlet—that he is
not a competent judge of the affairs of
the medical profession, as well as the
promise he made to confine his atten-
tion to his own trade.

Nor is this the only case in which
the writer has forgotten the real posi-
tion of the class of which he is a mem-
ber. He appears to have entirely over-
looked the unfairness of the mode and
extent in which they practise medicine,
to the serious injury of the licensed
apothecary. The position of the che-
mist and druggist of the present day is
almost exactly the same as that of the
apothecaries (at least, as far as they
were recognized by law) before the year
1815; and if it has never been disputed
that some measures were then neces-
sary for the security of the public
against the malpractices of the apothe-
caries, it can surely not be doubted that
some are requisite now to determine
what are the rights of the druggists,
who hold a similar position in the
present day, and to restrain them, as
far as possible, within the limits of
those rights. The writer of this
pamphlet may do his best to be figura-
tive and facetious at the expense of the
Apothecaries' Company, and to be
fiery at the quacks, but he should not
forget that the position of his own
class is more anomalous than that of
either, and that whatever be their
assumed functions their medical prac-
tice is more like that of the latter than
of the former class.

Chemists and druggists, as they call
themselves (we speak of course of only
the great body of them) have long
ceased to be chemists. As a body they
know no more of chemistry than they

do of astronomy. And even as drug-
gists, if this pamphlet may be
trusted, the knowledge the majority
of them possess is of that kind and
quantity so commonly met with—
enough to cheat with, but not enough
to prevent being cheated : they can all
adulterate their goods, but they do not
seem able, even when disposed to do it,
to determine how far others have
already adulterated them by any other
test than the relation which the asked
price bears to the market price of each
genuine article. This might have been
enough to call for legislative inter-
ference, seeing that they deal with goods
on which the health of every member of
the community is once or more in his
life dependent. But they go further; the
great majority of those from whom the
above picture of ignorance is drawn,
practise physic—

"Prescribe, attend, the medicine make, and
give"

—and this without even the plea of be-
nevolence which the good man of whom
the line was written might urge. It is
probable that the majority of what are
regarded as slight illnesses, and of those
little disorders whose sum determines
the length of man's life as much as the
rarer but more severe afflictions do, are
treated by druggists, who, so far from
being authorized to take the charge
and cure of disease, are even ignorant
of the nature of the means which they
make use of.

We say again, what we have re-
peatedly urged, that there cannot be
any reason why chemists should not
be prevented from practising medicine.
Either they should be restrained from
doing more than selling medicines ac-
cording to prescriptions, or if they may
be allowed to dispense on their own
recommendation, it should only be for
very slight cases, and they should be
prevented from doing even this until
they have shown, by passing a satisfac-

tory examination, that they may be
trusted not to do mischief. In a word,
those who are chemists only by name
should be compelled to become, in fact,
either apothecaries or druggists; they
should have licenses either to practise
and sell medicines, or to do the latter
only. In the former case they might be
placed under the superintendence of
the Apothecaries' Company ; in the
latter, as the writer of the pamphlet
suggests, under that of some authorized
body, with powers similar to those of
the Excise.

THE

LATE INQUEST AT KENSINGTON.

Last week we gave a short account of
the inquest held at Kensington on the
body of Elizabeth Friry. On Thurs-
day, the 12th inst. another investiga-
tion into the same case took place
before the Board of Guardians of the
Kensington Union, and Sir E. Head,
the metropolitian assistant commis-
sioner. Scarcely any new facts were
elicited, and the investigation, like the
inquest, terminated by a censure on the
union surgeon, and the relieving officer.

The merits of the question lie in a
nut-shell. The grand boast of the Poor
Law Commissioners, perhaps the only
boast founded on truth, is that they have
lowered the rates. Yes, they are lowered,
and it would be strange indeed if they
were not. The same plan of minimi-
zation of the rates might be extended
until they differed from zero, to use a
mathematical expression, by a quantity
less than any that can be assigned. Let
all the Union Bastiles, for instance,
be under ground, and we would gua-
rantee a considerable diminution in the
number of inmates. That this lower-
ing of the rates has been accompanied
by a frightful increase of the sufferings
of the poor—of misery not the less
acute because the corpses of its victims
are commonly huddled into their graves
without comment—is most true ; but
still the consoling arithmetical fact re-
mains that the rates are lowered. When
we examine how the reduction has
been effected, we immediately find that
one of the chief instruments of economy
has been a harsh tone towards the poor.

The objects to be relieved, are not, as the Malthusians always insinuate, machines which advance with unerring aim towards the proffered gruel, but living creatures as capable of being hurt by scorn and contempt as many an assistant-commissioner. It is not to be supposed, however, that this desirable or rate-lowering manner has the same precise hue in all who adopt it. The polished Malthusian expresses his regret that his painful duty will not permit him to allow tobacco to enter a workhouse; while a relieving officer bids applicants for bread begone in the plainest English : the spirit is the same in both. There is a pretence which we have all heard a thousand times, that workhouses, as now managed, are exquisite tests of destitution ; fine sieves by which our Poor Law people can infallibly separate the impostor from the meritorious poor man; the starving labourer passes through, while the mere idler remains upon the wires. In practice, however, these coarse bolters do not succeed ; rather than submit to the shameful rigour of a Union penitentiary, the poor prefer dying of want in their own hovels. It is obvious to every impartial person that catastrophes like the one at Kensington must be of common occurrence, and that the prominent distinction of the case is Mr. Wakley's activity in bringing it to light. Hence the true palliation of the conduct of the surgeon and relieving officer at Kensington—if palliation it can be called—is to be found in the admitted facts that "lower the rates" is the never ceasing cry of their masters the Poor Law Commissioners ; and that the only way of doing this effectually is by scaring away the suffering poor. Instead of taking up this line of defence, however, Mr. Wright sends a letter to the Board of Guardians, in which he says, among other things, " It is not that I feel individually the dastardly acrimony of a party who at once avow their disloyalty to their Sovereign by the reckless opposition to the New Poor Law—to a bill, which, whatever be its merits or its defects, is nevertheless the established law of the land." Such trash as this does not mend the matter in the least. The real excuse should be, that in order to reduce the rates to a minimum, or " carry out the new Poor Law," as it is often termed, the indigent must be treated with extreme rigour; and it is not every one who can give nothing with the suavity of a courtier, or who even knows how many degrees below zero, are esteemed the proper temperature of charity at Somerset House. It would seem from this investigation that the rule of admitting urgent cases into workhouses without an order is by no means universally acted on : the same thing came to light in the investigation of the case of the young woman, who was lately delivered in a cab, having been refused admittance into Lambeth and St. James's workhouses ; so that any catastrophe may happen while an order is being procured.

The observations of Sir E. Head on the case of Elizabeth Friry were just and feeling, and if commonly made by Commissioners and Assistant-Commissioners, would go far to disarm opposition to the New Law, by humanizing the spirit in which it would be administered. Let us trust that it may be so ; and instead of the Harpagon howl of " Lower the rates," may we hear the more English cry of " Relieve the suffering!"

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Nov. 10, 1840.

Dr. Clendinning in the Chair.

A Fourth Memoir on some Principles of Pathology in the Nervous System : viz. on the Plan of Observation to be adopted in the Investigation of the Diseases of this System. By Marshall Hall, M.D. F.R.S.

After having alluded to the subject of his former memoirs, the author observes that it is impossible now to observe or investigate a disease of the nervous system, without a constant reference to the distinctions he has proposed in regard to its physiology and pathology. He observes, sufficient has been done to shew that we must, in all such investigations, view the nervous system as subdivided not into the cerebro-spinal and ganglionic, but into the cerebral, the spinal, and the ganglionic ; and that, in considering each disease of the system, we must trace its influence distinctly in these three subdivisions of that system. We must inquire — 1. What are the diseases of the cerebral, of the true spinal, and of the ganglionic subdivisions of the nervous system ? and 2. What is the influence of disease of one of these on the other two ? and in what order is that

influence manifested ? The replies to these questions give the *diagnosis* and the *prognosis*.

In hemiplegia the danger is in proportion to the degree in which the true spinal system is involved with the cerebral. Is there stertor ? is there dysphagia ? are the sphincters affected ? there is great danger. Do these symptoms continue in spite of active remedies ? the case is fatal. What is the *rationale ?* The true spinal system has been affected by the cerebral disease, by counter-pressure. If this be from *congestion* merely, bloodletting relieves it, and the symptoms cease. If the symptoms do not cease, the fear is excited that not congestion but effusion is the immediate cause.

In a case of the purest apoplexy, that following a violent fit of epilepsy, the eyelids did not close when the eyelashes or the conjunctiva was touched ; nor did dashing cold water on the face induce sobbing. Forty ounces of blood were taken from the arm, and these functions of the true spinal system were at once restored. It is unnecessary to state what influence these facts had on the diagnosis and prognosis.

In a case of hydrocephaloid disease, the eyelids gaped and remained motionless when approached and touched with the finger. On giving cordials, the true spinal system recovered its functions, and the little patient recovered forthwith.

The first degree of apoplexy exists as a purely cerebral affection, the second involves the true spinal marrow, and the third the ganglionic system. Coma, stertor and dysphagia, bronchial rattle, &c. respectively denote these several degrees of this malady.

Tetanus, on the other hand, is at the first a purely spinal affection ; the cerebral functions are unaffected ; during its course the cerebral and the ganglionic subdivisions of the nervous system become involved.

Epilepsy seems to occupy the limits of the true cerebral and spinal system. The first symptoms are, in a multitude of cases, if not in all, affections of the true spinal : the effects of these are seen in the cerebral subdivisions of the system.

The paper discusses the subject of counter-pressure, in cerebral diseases, on the true spinal marrow ; and the peculiar effect of exposure to cold, in first inducing paralysis and then spasmodic affection. These points were illustrated by a series of facts and observations.

The author concluded by presenting a list of the points to be noticed in investigating the diseases of the nervous system, in the form of a table :—

1. The cerebral symptoms,
2. The true spinal symptoms,
3. The ganglionic symptoms, distinctly.
4. The degree of complication of these.

5. The supervention of one or two of these upon the third previously existing.

6. The condition of the muscular irritability.

7. The condition of the reflex and retrograde actions.

8. The action of the *vis nervosa*.

9. The effects of emotion.

10. The power of volition.

11. The probable influence of counter-pressure.

12. The condition of paralysis and of spasm, and the changes in these.

Some discussion followed, but not of a nature to throw any farther light upon the subject.

RESULTS OF M. ORFILA'S TOXICOLOGICAL EXPERIMENTS.

WE return to this subject, and give the results, such as we have seen them, and as they have been publicly announced by the professor, with a view to prove on the one part that arsenic and tartar emetic, when absorbed, are mingled with the blood, pass successively through all the organs, and are rejected more or less rapidly, as excrementitial products, through the urines ; on the other, that the treatment by tonics is disastrous, while the treatment by diuretics is regarded as most advantageous by M. Orfila.

All the dogs to which small doses of arsenical acid dissolved in water were administered, and which were subsequently left to themselves, whether they were bled or gorged with hot water, with a view to excite and augment the urinary secretion, were cured. All those, on the contrary, which took the same dose of arsenical acid, and were treated by tonical medicaments, died. One dog, which, without being poisoned, had the tonic potion of M. Roguetta passed forcibly thrice successively into his stomach, died in a few hours ; but it must be confessed that the dose was enormous. What are we to conclude from results in appearance so positive and conclusive ? Our embarrassment will be readily conceived. M. Roguetta has made, before a commission of the Academy of Medicine, some experiments, by which he contends that he has established that all the dogs which took his tonic medicaments were cured, whilst all those which he treated by bleeding, according to M. Orfila's plan, died, either from the effects of the poison, or of the particular mode of treatment. M. Orfila on his side asserts, that he has proved that all the dogs which he had treated by bleeding and hot water have been cured, while those to which he administered tonics, died. Between Hippocrates, who says " Yes," and Galen, who says " No," we have always said both " yes" and " no." In effect, dogs poisoned

by arsenic become cured by all modes of treatment, provided they vomit, that is to say (if the word be permitted us) provided they "disempoison" themselves. Diuretics may be useful when they aid the animal to rid himself, through the urinal process, of the quantity of poison absorbed. But these same diuretics may be injurious when, at the same time that they expel the poisons absorbed ; they dilute that which still remains in a state of powder in the digestive system, M. Orfila himself admitting that, in order to act, arsenical acid, which is little soluble by nature, must in the first instance be dissolved. On the other side, tonics may be advantageous when they give the animal new strength to vomit, but they become pernicious when fever and inflammation have been already produced by the action of the poison.

M. Orfila established—1, that the elimination of poison through the urine is much more rapid in the case of tartar emetic than of arsenic ; 2, that this elimination takes place from the commencement of the poisoning, and is continued so long as the organs contain poison ; 3, and lastly, that arsenic or antimony remains in the interior organs, the liver especially, even when no traces of it are longer to be found in the excrementitial liquid. His experiments all confirmed these results, whether they treated the urines of dogs which had survived the poisoning, or operated upon the urine or the organs of those which were slain, or had died within one or six days after imbibing the poison. Moreover, at the request of several physicians, it was established that the urines of several sick persons who had taken either emetic or arsenic as medicaments, exhibited, when submitted to Marsh's apparatus, traces by no means equivocal of arsenic or of antimony,

It is obvious how important these results are, either therapeutically considered, or in connexion with legal medicine. The physician, when called to the bedside of a patient whom he has reason to believe poisoned, may at once, by a simple chemical analysis, assure himself whether these suspicions are well founded. But M. Orfila did not confine to this the important disclosures which he made to his audience. This part of his experiments or demonstrations, of which we have still to give an account, is neither the least important nor the least filled with interest.

The first care to be taken in a course of medico-legal experiments is to make certain of the purity of the reactions employed. For Marsh's apparatus, M. Orfila observes, that the precautions to be taken are very simple. Zinc and water are put into a flagon. Some pure sulphuric acid is added, and the as is inflamed. If the jet of this flame

makes no deposit on a porcelain plate, all the reactions employed are pure, and Marsh's apparatus may be used with all safety. We have no objection to make to this reasoning. But we must observe, that it is not every brilliant spot which is arsenical ; and this is confessed by M. Orfila himself. There are employed for the treatment of arsenical matters, *potass à l'alcohol*, nitric acid, and nitrate of potass. We need scarcely add, that the utmost pains must be taken to secure the purity of these substances. M. Orfila ordered a kilogramme of nitrate of potash to be taken by chance from a druggist's, this nitrate being crystallized. 500 grammes of this nitrate of potash were decomposed, through exposure to heat, by 435 grammes of pure sulphuric acid, and yielded in Marsh's apparatus no trace of arsenic, while the second half of the same nitrate, with the addition of the hundredth part of a gramme of liquid arsenical acid, at once gave numerous metallic spots, whence the professor thought himself justified in concluding, that the common nitrate of potash, used for purposes of trade, when it is crystallised never contains arsenic. But M. Orfila also demonstrated by divers experiments that the peroxyde of common iron and that used by druggists almost always contains arsenic. In seeking for the origin of this poisonous substance in a medicament usually accounted an antidote, M. Orfila showed that it was owing to the pyrites of iron employed for the preparation of colcothar, which pyrites of iron is known to contain arsenic pretty frequently.

That there exist arsenical earths no one doubts. Arsenic is as generally diffused as iron, and iron is to met all through nature. But can the arsenic which exists in the earth communicate itself to a dead body ?" No," says M. Orfila ; and here are the experiments and reasonings on which he founded his opinion. He collected in different places, more especially in cemeteries, earths containing salts or arsenical composts; and in no instance did he obtain, by the exclusive action of boiling water, a *solutum* which in Marsh's apparatus yielded arsenical spots. Upon the other hand, he took seven pounds of earth from the cemetery of Mont Parnasse, diluted them with water, treated afterwards with boiling sulphuric acid for the space of 24 hours, and obtained from the *solutum* manifest traces of arsenic. Strong acids, therefore, are alone capable of decomposing or dissolving arsenical salts found in the earth, and water, even boiling, has no action whatever upon them. Unless we admit unknown reactions in the bosom of the earth, unless we suppose an intervention of electro-chymical forces to explain phenomena which we do not see, and which we cannot establish, it is impossible, says

" 7. Because it proposes to place the science and practice of Pharmacy under proper superintendence, by requiring all chemists and druggists to hold the license of one or other of the Councils; and by rendering it imperative on all persons who shall not have carried on the business of a chemist or druggist prior to the passing of this Act, to undergo an examination in accordance with the bye-law of the Senate, before receiving the license of the Council.

" 8. Because it provides for the publication of a British Pharmacopœia."

The Council, in stating their general approbation of the principles embodied in the Bill of Mr. Hawes, and of some of the more important features of that measure, beg to be understood as not by any means giving their implicit and unconditional assent to the whole of the propositions therein contained. Some of them would undoubtedly require to be considered, before bringing the Bill into parliament; others to be amended, or perhaps entirely withdrawn; and in some respects the Bill is defective on the ground of omission.

In the present position of medical affairs, and in the anticipation of a third Medical Bill, it would be eminently unwise and imprudent in this Association to pledge itself to the support of any particular measure; and the Council would strongly urge upon their brethren, in all parts of the kingdom, the expediency of withholding their positive adherence to any given plan of Medical Reform, until opportunity have been afforded the profession of ascertaining the number and nature of the bills which are likely to be submitted to Parliament.

The Council are furthermore of opinion, that a strenuous effort should be made to procure the introduction into the legislature of one bill and of one only. With this end in view, and in the hope of adapting such Bill, as far as possible, to the exigencies both of the public and of the profession, they give their cordial assent to the proposal of the British Medical Association, that delegates should be chosen by the different associations to meet in London for the purpose

of advancing the progress of medical legislation in the next session of parliament.

A letter having been read from the Secretary of the British Medical Association, relative to the appointment of delegates, it was resolved unanimously, on the motion of Sir John Fife, of Newcastle, seconded by Dr. Brown, of Sunderland, " That this Council do authorize their Secretary to proceed to London, as a delegate from this Association, appointed to co-operate with the representatives of other Medical Associations of the United Kingdom, in promoting the advancement of medical legislation.

LOOSENESS OF THE TEETH.

AMONG the various causes which produce looseness of one or several teeth, none is more common than inflammation of the alveolar processes and sockets. Sometimes this originates in disease of the tooth itself, or of the gums; but in other instances, the diseased process commences in the alveolar periosteum, and by spreading to the sockets and gums, it gives rise to great pain, swelling, and sponginess of the latter, while it eventually detaches the fangs of the teeth implicated in the attack, from the grasp of the sockets, and thus at last the teeth fall out, though in themselves they exhibit no appearance of decay.

The progress of the disease is accompanied by extreme pain, and as a puriform discharge oozes out from between the gums and the inflamed periosteum, many limit their attempts to local means, and often succeed in effecting a cure by frequent applications of leeches to the inflamed gum, and in very obstinate cases, by incisions freely made through the gums and inflamed periosteum. Last year a patient of mine was thus affected, and thus treated, and although under the care of a most skilful surgeon, and of an eminent dentist, he lost successively a left bicuspis and molar of the upper jaw. His sufferings were for a short time relieved by the extraction of each tooth, but in a few days became as agonizing as ever, when finding all the neighbouring teeth loose, and being told that they also must soon be drawn, he had recourse, in despair, to a celebrated homœopathic doctor, whose infinitessimal doses completely failed; for the patient's sufferings were produced by a direct physical cause, which lay far beyond the limits to which the influence of even the most powerful imagination can possibly extend. Happening to mention his wretched state to me, I immediately recollected, that a year before I had successfully treated him for a periostic affection of the sternum and ribs, and that hydriodate of potash was the medicine which served him most. I recommended him to use ten grains of it three times a day, and

in all parts of the United Kingdom irrespectively, would not deprive any existing University, College, or Hall, of the power to educate and to examine medical students; for by the concluding part of the clause, all candidates applying to be examined by the Councils would be compelled to produce evidence of having taken a degree in Medicine, or having passed an examination in Medicine or Surgery, before one or other of the institutions entitled to grant a diploma, certificate, or letters-testimonial, at the time of the passing of this Act. No University, College, or Hall, would, however, (after the publication of the bye-laws of the Senate,) have power to grant any diploma, certificate, or license, except under the provisions contained in this Act.

had the satisfaction of perceiving a daily improvement, so that pain and inflammation soon ceased, and in about ten days the teeth were all fastened.

The periostitis to which this gentleman was liable was of a rheumatic nature ; otherwise his constitution was sound, and he was only thirty-four years old.—*Dr. Graves, in Dublin Journal.*

GOUTY REDNESS OF THE NOSE.

A LADY of a decidedly gouty habit, aged sixty, applied to me under the following circumstances : for the last two months she had become liable to a daily paroxysm, which observed the following course. About three o'clock in the afternoon, her nose began to grow hot, and the heat continued for four or five hours, the part becoming first of a bright, and then of a purplish red colour, which spread to the upper portion of her cheeks, and was accompanied by some uneasiness, but no pain, and always subsided about the same hour in the evening. I advised small doses of colchicum, but have not learned the result. Within the last ten years, 1 have seen, in private practice, three examples of hypertrophy of the finger tops, and corresponding hypertrophy of the nails, two occurring in delicate, and one in a phthisical habit. In all these patients the remaining parts of the fingers were emaciated, while the tips of the fingers were much, and abruptly enlarged, especially in the transverse diameter, the nails being also of greater size, considerably longer, broader, stronger, and more curved than natural ; in all these, was evident increase in the capillary circulation, and the tips of the fingers were red, tender, and painful, and often bathed in sweat ; a minor degree of this affection, cha acterized however only by strong aduncated nails, while the tips of the fingers are much less emaciated than other parts of the hand, feel hotter to the patient, and sweat more, is frequent in phthisis.—*Dr. Graves, in Dublin Journal.*

VACCINATION FEE AT BRENTFORD, HALF-A-CROWN.

To the Editor of the Medical Gazette.

SIR,

By way of supplement to the communication you did me the favour of inserting at page 174 of the present volume, I enclose a circular which has been issued within these few days, announcing the consent of the Guardians and the sanction of the Commissioners to the terms proposed by the combined practitioners of this Union. You will perceive that in addition to the allowing of *half-a-*

crown per case, the privilege of vaccinating under the act is not restricted to the parochial surgeons, but is *open to every qualified practitioner* throughout the Union.

This triumph over the misinformation which dictated the original offer of the Commissioners has been achieved only by the unanimity of the thirty-three medical men of the Brentford Union, not a single one of whom has acted in opposition to the wishes of his professional brethren.

With many thanks for your ready publication of our proceedings, I remain, sir,

Your obliged and obedient servant,

FRANCIS A. B. BONNEY.

Brentford, 18th Nov. 1840.

BRENTFORD UNION.

Brentford, Nov. 11, 1840.

Gentlemen,—The Poor Law Commissioners having sanctioned the proposal to throw open the performance of Vaccination to every duly qualified Medical Practitioner in the Union at Two Shillings and Sixpence for each successful case,—

I am requested by the Board of Guardians to apply to you, to be informed if you are willing to enter into the Contract prescribed by the Commissioners on the terms named ? —And to beg your reply in writing on or before the 1st day of December next.

I am, Gentlemen, your obedient servant,

G. CLARK.

To the Medical Practitioners within the Union.

HENLEY ON THAMES.— VACCINATION.

THE medical gentlemen employed in the care of the poor of this Union, after several unsuccessful exchanges of proposals with the guardians, as to terms for vaccination, have felt themselves, in conjunction with all the medical men of the town, and some others of the neighbourhood, called upon to condemn and regret the offer of eighteen-pence per case, as not only falling short of remuneration altogether, but as offering an injury to the credit and character of the profession. The offers of two shillings and sixpence for cases at their respective surgeries, and three shillings and sixpence for the more distant, are unanimously determined upon by the medical gentlemen, and have been hitherto declined by the guardians.

They cannot but hope that their medical brethren will act with equal unanimity, and consideration of what is due to the character of their profession, whose honourable conduct, and disinterestedness in the ministration of vaccination heretofore, has been highly complimented by the authors of the

eighteen-penny fees! It is no reflection upon them that they no not understand, the delicate, important, and, in rural districts, troublesome and laborious, duty of efficient vaccination.

Henley on Thames,
Nov. 17, 1840.

UNIVERSITY OF LONDON.

SECOND EXAMINATION FOR THE DEGREE OF BACHELOR OF MEDICINE.

November, 1840.

THE following is a list of the Candidates who passed this Examination, and who have consequently had conferred on them the degree of Bachelor of Medicine.

First Division.—Philip Burnard Ayres, University College ; John Charles Bucknill, University College ; John Carey, Richmond Hospital, Dublin ; Anthony French Carpenter, School of Physic in Ireland ; Henry Cooper, University College and Middlesex Hospital ; Stephen Jennings Goodfellow, St. Bartholomew's Hospital ; Thomas O'Meara, University of France, and Mercers' Hospital, Dublin ; John Paddon, University Coll. ; Rich. Quain, University College ; William Rayner, University Coll.; Robt. Russell Sewell, University College ; John Douglas Strang, University College ; Jonathan Mason Waddy, St. Thomas's Hospital, and Webb Street ; Thomas Williams, Guy's Hospital, and Webb Street ; Edwin Wing, School of Physic in Ireland.

Second Division. — Edward Goodeve, Bristol (Medical School) ; Robert Hutchinson Powell, Digges Street, Dublin ; and Apothecaries' Hall, Ireland ; Wm. Tyler Smith, Bristol (Medical School) ; David Unwin, University College.

SECTION OF THE DORSAL MUSCLES
FOR THE
CURE OF LATERAL CURVATURE OF THE SPINE.

To the Editor of the Medical Gazette.

SIR,

SINCE I performed the operation of dividing the dorsal muscles for the cure of certain curvatures of the spine I have been overpowered by letters from all quarters, in which I am requested to explain the mode in which the operation is performed, and the kind of curvatures for which the operation is suitable. As my avocations will not permit me to answer the letters of my respected correspondents individually, will you have the goodness to allow me, through the medium of your publication, to inform my correspondents that I shall take an early opportunity of transmitting the case to which their letters

refer to the MEDICAL GAZETTE, when I hope I shall be able to give a satisfactory answer to all their interrogatories.

I am, sir,
Your obedient servant,
ROBERT HUNTER.
33, North Hanover St., Glasgow,
Nov. 11, 1840.

LORD RECTOR, GLASGOW.

MEETING IN FAVOUR OF SIR ASTLEY COOPER.

MONDAY a meeting of the members of the medical profession, and of the students of the University favourable to the election of Sir Astley Paston Cooper, Bart., as Lord Rector, was held in the surgery class-room of the College, at three o'clock, and was numerously attended, the class-room being crowded to overflowing by a mixed audience of medical students, graduates, and students in the different classes of the College. The proceedings were conducted with order and decorum, and the feeling of the meeting was unanimous in favour of the return of Sir Astley P. Cooper to the rectorial chair.— *Glasgow Constitutional.*

The election has since taken place, and in favour of Lord Breadalbane. The numbers were—Lord Breadalbane, 250 ; Sir Astley Cooper, 111 ; Duke of Wellington, 105.

ROYAL COLLEGE OF SURGEONS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. WATSON.

LECTURE X.

Inflammation continued. Buffy coat of the blood. Terminations or events of inflammation. Resolution; delitescence; metastasis. Effusion of serum. Effusion of coagulable lymph, or fibrin. Organization of this lymph. Suppuration. Ulceration.

IN the last lecture, after giving a very general sketch of the phænomena of inflammation, I particularly considered its four characteristic symptoms—pain, heat, redness, and swelling : and endeavoured to describe the changes that take place in an inflamed part, as they are seen through a microscope.

Buffy coat of the blood.—There is one very remarkable and important circumstance which is not often absent in cases of inflammation, but which hitherto I have barely mentioned : I mean a peculiar appearance of the blood itself after it has been drawn from a vein. A portion of the fibrin at the upper surface of the coagulum parts with its colouring matter ; so that upon the deep red clot there is to be seen a layer of a yellowish, or sometimes of a bluish white colour, varying in thickness from a line or two to perhaps three-fourths of an inch. This uppermost whitish layer of the coagulum is called in this country the *buffy coat* of the blood. Sometimes the surface of the buffy coat is flat and wide ; but often it is contracted and concave ; *i. e.* the diameter of the buffy surface is less than the diameter of the lower portion of the clot, and it is hollowed out

into a cup-like form. Accordingly the blood is said, in these circumstances, to be both buffed and cupped. The formation of this buffy coat appears to be favoured by many circumstances which have nothing to do with the disease under which the person may be labouring ; such as the size of the aperture in the vein, the manner in which the blood flows, the form and size of the vessel that receives it : but it does not occur at all except in certain conditions of the system ; and it belongs so especially to the state of *inflammation*, that blood having the buffy coat upon it is often spoken of as *inflammatory blood*, or, with less propriety, as *inflamed blood*. Both these expressions indeed are incorrect, for inflammation sometimes exists without buffy blood ; and buffy blood sometimes occurs without inflammation. The phænomenon is, however, upon the whole, a very valuable index of the nature of many cases of disease, and an important guide in their treatment.

Now this crust, or upper layer, or buffy coat, consists of pure fibrin, mixed with a certain quantity of serum, which M. Gendrin says is fuller of albumen than the rest of the serum. You will not fail to notice the great analogy that subsists between the buffy coat and the coagulable lymph poured out in inflammation, either into the texture of the part ; or (as I shall shew you more particularly by and by) upon its surface, forming what are called false membranes. Both in appearance, and in chemical composition, the two seem to be identical ; and no doubt exists in my mind of their being actually the same substance : the separation in the one case taking place from the blood while contained in its proper vessels ; in the other case from the blood after it has been removed from the body.

There has been a great deal of speculation among pathologists as to the cause of this buffy coat. From its situation it is plain that gravity has something to do with its

formation : that the red particles, leaving the colourless fibrin before it coagulates, sink downwards by their own weight. But though the *subsidence* of the red particles is occasioned by their greater specific gravity, their *separation from the fibrin* is not to be explained upon that principle alone. If it were, then it would follow that the slower the coagulation of the blood, the more time would there be for the sinking of the red particles, and the thicker and more decided would be the buffy crust : and it used to be supposed that this was the true explanation of the phænomenon. Careful observations, however, have shewn that the formation of the buffy coat often takes place when the coagulation of the blood is unusually rapid. Dr. Davy and M. Gendrin both state, as the result of much attention to the subject, that the coagulation of blood drawn from a vein during inflammation begins sooner, and is more quickly completed, than that of healthy blood. But certain observations made and published by Dr. Stokes have settled this question. He noted the appearance of the blood in 27 cases. In 15 of these the buffy coat presented itself ; in 12 it did not. Now in 3 of these 12, the coagulation of the blood did not begin till from 20 to 40 minutes after it was drawn ; and in 4 others there was no coagulation for 8 minutes. So that there was plenty of time for the red particles to have left the fibrin, and subsided ; but they did not do so. On the other hand, in 12 out of the 15 cases in which the blood *was* buffed, the coagulation took place in 5 minutes ; and in the remaining 3 it was only delayed 14 minutes.

The slowness of the coagulation, therefore, although it may and doubtless does *favour* the subsidence of the red particles when they have a tendency to subside, cannot be regarded as the cause of the buffy coat. The red particles very soon begin to subside when they subside at all : you may tell, immediately after it has been drawn, and prior to any coagulation, that blood is about to buff, by a peculiar bluish hue on its surface. A German writer, Schroeder Van der Kolk, has stated observations to the same purpose, shewing that in the blood abstracted by venesection during inflammation there is an unusual disposition to a separation of the fibrin from the red particles : a sort of *repulsion* between them. This separation takes place in mere films of blood, so thin as not to admit a buffy stratum to be laid above a red stratum. The fibrin and red particles then separate from each other laterally by horizontal movements, and the films acquire a speckled or mottled appearance, quite as characteristic of the state of the blood as the buffy coat itself.

That the formation of the buffy coat depends, however, upon some *vital* change in

the blood appears probable from this—that it will sometimes vary greatly in different portions of blood abstracted at the same bleeding. Thus if the blood be received into four different cups in succession, it will perhaps be buffy in the first, and in none of the others ; or it will be buffy in the last only ; or in the second and third only, the first and fourth cups being free from buff. Attempts have been made to explain these rapid variations. Some have fancied that the inflammatory state having been remedied by the removal of a certain quantity of blood, the blood that flows subsequently is *therefore* without the usual index of the presence of inflammation ; but this explanation will not apply at all to those cases in which the portions last drawn are the only portions that exhibit the buffy crust. Others have suggested that the state of the nervous system is principally concerned in these sudden changes—that the depression caused in the outset of the bleeding by fear, and the faintishness produced towards its termination by the loss of blood, may prevent the appearance of the buffy coat on the first and last cups, when it shews itself only in those that are intermediate between the first and last. We cannot rely much on these hypothetical explanations : I mention them to impress upon your memory the facts which they are intended to explain.

There are two or three different forms presented by buffy blood ; and with these you ought to be familiar.

In one form the buffy coat is thick, tough, contracted, puckered at its circumference, and its surface is cupped. There is a complete separation of the red particles, and a strong aggregation of the particles of the fibrin among themselves. The red portion of the coagulum is also, in these cases, round and contracted, of a globular shape, firm, detached from the sides of the vessel, and floating, generally, in transparent serum.

This is usually seen when the inflammation is violent ; when it occurs in strong and vigorous constitutions ; and more I believe when it has its seat in certain tissues, in fibrous and serous parts especially.

In another form, the whole coagulum is large, like a cake, or of the shape of the vessel containing it, not so much collected into a spherical form : and the buffy coat is thin and flat, and easily broken. Here there is an imperfect separation of the colouring matter from the fibrin, and no great aggregation of the particles of the latter. This kind of buffy blood is apt to accompany slight or partial inflammation.

In a third form, the buffy coat is thick and abundant, but it is flat and soft, loose and flabby, like paste, and the coagulum often adheres by its edges to the vessel in which the blood has been received : there

has been considerable separation, and but slight aggregation. The serum is apt to contain a few red particles distinct from the clot. Such blood is commonly said to be *sizy.* Dr. Alison states that when it is observed, some other cause of general disorder of the system (continued fever, for example) usually co-exists with the local inflammation.

It is a curious fact that blood drawn by leeches never exhibits the buffy coat. It seldom appears (yet I have seen it) upon blood that has been removed by means of cupping glasses.

Arterial blood is liable to the buffy coat. I have myself twice at least seen the buffy coat on blood drawn from the temporal artery. One of the patients was violently maniacal when the blood was taken. The other was labouring under acute inflammation of the membranes of the spinal cord, of which inflammation he died.

Blood is more likely to buff, *cæteris paribus,* when it is made to flow in a full stream, and when it is received in a deep and narrow vessel.

On the other hand, the formation of the buffy coat appears to be hindered, when the blood trickles from a small opening in the vein, and when it is caught in a large flat vessel. . It is said also that the buffy coat may be prevented by adding to the blood a solution of caustic potass ; by keeping it for some time in a state of agitation ; by receiving it in a very cold vessel ; or by suffering it to fall from a height of three or four feet. In this last case M. Gendrin supposes that the prevention is owing partly to the agitation which the descent of the stream produces in the blood already in the vessel, and partly to the circumstance that the blood is cooled as it passes through the air.

It is seldom, I believe, that the buffy coat appears on blood drawn at the very outset of inflammation ; generally a day or two elapses before it shews itself.

I have dwelt the longer upon this peculiar appearance of the blood, because it really is of very great importance in determining the nature of various complaints, and in directing our treatment of them. Speaking generally, when a given organ is inflamed, the buffy coat is more marked in proportion to the intensity of the inflammation : when the organ is not known, it is more likely to be of a fibrous or a serous texture, in proportion as the blood is more decidedly buffed. The appearance of the buffy coat is especially valuable as an indication of treatment in cases concerning which we are in doubt, whether they are inflammatory or not. On the other hand, if we have good evidence, in other symptoms, of the existence of inflammation, we are not to be shaken in our opinion by the absence of the buffy coat.

Inflammation may certainly exist without it. I am not speaking now of slight cases of inflammation, which do not disturb the general system. You would not look for buffy blood in the inflammation that supervenes on a cut finger, or in a small boil ; but in serious inflammation, attended with pyrexia, the buffy coat may be wanting. It is not unfrequently absent in inflammation of the mucous membranes, especially in inflammation of the mucous lining of the bronchi.

I stated before—what it is quite necessary to remember—that buffy blood is not confined to cases of inflammation. The blood of persons affected with general plethora is often found to present a buffy coat : and the same thing is true in respect to pregnant women.

Buffy blood is no necessary measure of the *danger* of the disease. The blood drawn in acute rheumatism is always very much buffed and cupped : yet so long as the disease is confined to the joints, it is quite free from danger.

Neither is the appearance of buff on the blood, taken by itself, a sufficient warrant for abstracting more blood : for the blood will sometimes, in common inflammation, continue to be buffy, long after it has ceased to be useful, or safe, to bleed the patient.

Events of inflammation.—Some pathologists enumerate several *terminations* of inflammation. Others quarrel with that word, as inappropriate ; alleging, with great truth, that the inflammation does not necessarily cease or terminate whenever these so-called "terminations" happen. Some of them are in fact "co-existent states, or successive stages in the progress of the same inflammatory disease." It has been proposed to speak rather of the *local effects* of inflammation ; but even this phrase is not free from objection, for sometimes (though rarely) there are no local effects produced, beyond the four symptoms which characterize the inflammation itself. I think the *events of inflammation* is an expression not open to similar cavils. I have no ambition to introduce new modes of speech, unless when those that are already in use are inexact or inapplicable. It is enough if you clearly comprehend the meaning of the terms I employ. Among the events of inflammation I include only the *local* changes observed in its course. To those which are constitutional I must afterwards revert.

You will recollect that I did allude, in the last lecture, though in a very brief manner, to these local events of inflammation. Their frequency and importance renders it necessary that we should consider them somewhat more particularly.

Resolution.—One of these events is the simple subsidence or *resolution* of the in-

fl immation : this may strictly be called a *termination* also. The congestion of the blood-vessels increases till the blood stagnates in some of the capillary canals towards the centre of the affected part, which is then said to be *inflamed;* but the disease goes no farther ; there is no escape of the blood, or of any part of the blood, or of any of the constituents of the blood, beyond its natural channels ; or, at any rate, there is no *sensible* evacuation into the inflamed tissue, or next to none. The inflammation begins to recede ; the stagnant blood is again set in motion ; if there have been some slight effusion, it is reabsorbed ; the rapidity of the circulation in the surrounding vessels diminishes ; and the part returns, in all respects, to its former condition and integrity. This may be considered the spontaneous cure of inflammation ; and to this event there seems to be always a natural tendency. It may be promoted sometimes by art.

Delitescence and metastasis.—When the process of resolution is unusually *sudden* and *rapid,* (as it occasionally is, the well-marked phænomena of inflammation completely disappearing in a few hours,) it is called by our neighbours, the French, *delitescence.* And when the symptoms of inflammation thus suddenly desert one part, and shew themselves immediately afterwards in another, (as not unfrequently happens in respect to the joints in acute rheumatism, and between the parotid gland and the testicle or mamma in the mumps,) *metastasis* is said to take place.

This transference, as it were, of morbid action, from one part to another, is a very curious circumstance. It is one which we sometimes endeavour to imitate. We excite inflammation upon the surface, where we know its effects will be of comparatively little consequence, in the hope of *diverting* it from some internal organ in which it threatens to work serious or even fatal changes. We follow the same principle perhaps where we apply purgative medicines to the mucous membrane of the alimentary canal. To denote this mode of cure, by stimulating distant parts, the terms *counterirritation, derivation,* and *revulsion,* are employed.

Most commonly, even under moderate inflammation, *some* amount of extravasation takes place into the texture or from the surface of the part.

Serous effusion.—The first effect or event of that kind which we notice, is the pouring out or *effusion* of *serous* liquid. The liquid is so like the serum of the blood, that it is called serosity or serous liquid, and there can be no doubt, I conceive, that it consists of the serum of the blood, slightly modified perhaps. You will recollect my stating that the swelling which accompanies phlegmonous inflammation is not equally firm throughout the whole extent

of the inflamed part; that it is hard in the centre, softer towards the circumference ; and that in the latter situation it sometimes retains for a few seconds the impression of one's finger ;—*pits.* Now this results from the effusion of serous fluid in the cellular tissue immediately surrounding the part inflamed : it is neither more nor less than *ædema :* œdema, (which may exist also quite independently of inflammation) being a filling or infiltration of the cellular tissue with serous fluid. Anasarca is an example of the same state, on a larger scale. Now anasarca is very constantly produced by some impediment to the passage of the blood along the veins ; the serous portion of the stagnating blood transudes through the coats of the vessels : and I apprehend that the same explanation may be given of the less extensive œdema which takes place around a phlegmon ; the blood being stagnant in the neighbouring capillaries.

But whatever may be the intimate cause of serous effusion, it is one of the earliest events of inflammation ; and in some cases it is its most important event, producing, mechanically, new symptoms, and giving rise to conditions of the most perilous kind. The quantity of serous fluid poured out in a short time is often immense. One of the pleuræ may be thus filled in a few hours, and the whole of one lung strongly compressed, and the respiratory apparatus reduced to one-half of its customary efficiency. And if inflammation and effusion should take place on both sides of the chest at once, if *double pleurisy* should occur, as it sometimes does, the patient must presently perish by apnœa, unless his condition is recognized, and free vent is given to the fluid. More than once or twice have I seen persons snatched from the brink of suffocation by what is called *tapping* the chest. Fatal coma is no uncommon result of the effusion of serosity, as an event of inflammation, into the ventricles of the brain.

Even in the cellular tissue, where it is properly enough called œdema, a very trifling amount of this serous effusion may be sufficient to destroy life : when, for instance, it takes place into the submucous cellular tissue of the glottis, closing up by its pressure the little chink, the rima glottidis, and suffocating the patient after another fashion. Here also art may come to the rescue : an *artificial* chink or hole is made for the entrance and exit of air, below that part of the larynx in which the disease is situated, and the patient is delivered from imminent death. I have had two cases under my own care, and have seen several others, in which life *was so* preserved. I allude to such cases now, merely to convince you of the importance of attending to this event of inflam-

ation, and of studying the indications of its
xistence.

Sometimes some of the small vessels give
ray, and *hæmorrhage* into the part becomes
n event of inflammation. Some slight de-
ree of this occurs probably in most cases :
nd we frequently find that the colouring
natter of the blood is mixed with the other
ffusions, giving to the serous liquid a deep
nge of red.

I hinted before, that we must not infer
nflammation from the presence of serous
ffusion *alone*. Serum will exude, I be-
eve, from loaded veins, even after death ;
ut this never can be much in amount. It
certain that dropsical effusions may be,
nd very often are, the result of congestion
f a purely mechanical kind.

Effusion of coagulable lymph.—A third
vent of inflammation is the effusion of what
called *coagulable lymph*, which, as I ex-
lained to you before, appears to be nothing
se than the fibrin separated from the other
onstituents of the blood, and concreted. It
poured forth, at first, in a state of solution,
: in a soft semi-fluid condition, and mixed
ith more or less serosity : but the more
uid parts of the effusion are either soon
absorbed, or soon separate themselves
om the lymph, which becomes firmer, and
length solid. The hard central portion
a phlegmon, in its earlier stages, owes its
ardness to the presence of coagulable lymph
the natural interstices of the inflamed
rt ; and a similar interstitial deposit of the
me substance is common in various parts
the body, as a result or concomitant of
flammation. What is called hepatization
the lung is one instance—the spongy
xture of the lung is blocked up and solidi-
d by this lymph. In certain cases of
ysipelas, as well as in phlegmonous inflam-
ation, the subcutaneous cellular tissue is
ndered dense and hard in the same way.
he white opaque spots which are often seen
on the cornea are produced by lymph
terposed between the layers of that natu-
lly transparent structure. But the most
riking examples of the effusion of coagu-
ble lymph are to be seen upon the surfaces
inflamed membranes : it forms a web or
yer which by degrees assumes, itself, a
embranous appearance; and is accordingly
lled by morbid anatomists a false or an
lventitious membrane. Sometimes several
yers of this kind are spread over each other,
rming adventitious membranes of great
ickness. When coagulable lymph is thus
oured out between membranes that are
bitually in contact with each other, it
ten causes them to cohere together—just
two leaves of a book may be made to
ick together by a layer of paste or glue put
tween them. This is very common indeed

with serous membranes, especially the pleuræ,
the pericardium, and the peritoneum. Lymph
is said also to be poured out, under violent
inflammation, from mucous surfaces. In
croup, the interior of the trachea is inflamed,
and a substance exudes which assumes a
membranous form, and adheres more or less
firmly to the sides of that tube, or is coughed
up in ragged fragments. A similar effusion
takes place occasionally from the mucous
lining of the alimentary canal, and is ex-
pelled, with the other contents of the bowels,
in shreds, or in tubular portions, which are,
in fact, casts of the interior of the gut. I
say *coagulable lymph* is *said* to be thus poured
out ; but it is more than doubtful whether the
false membranes in these cases are really com-
posed of fibrin. Similar films form within the
uterus, and are moulded to the exact shape
of its cavity, and marked with indentations
that correspond to its rugæ ; and these mem-
brane-like casts are at length separated and
extruded. These last are not very common ;
but I shew you one which came from the
uterus of a young woman who was a patient
o mine in the Middlesex Hospital not very
long ago. You may see lymph deposited
like beads, upon the anterior surface of the
iris under inflammation ; or glueing its pos-
terior surface to the crystalline lens behind
it, and rendering the pupil irregular, and
sometimes immoveable. The internal surface
of the heart, and especially its valves, are
often studded with portions of lymph much
resembling warts. When the opposite sides
of an artery are brought together by a liga-
ture, they inflame, and become united by the
same medium. Coagulable lymph is effused,
in the course of a few hours, upon the edges
of a cut wound ; and they adhere, under
favourable circumstances, when placed in
mutual apposition. This surgeons call union
by *the first intention :* and the inflammation
which is accompanied by this kind of exuda-
tion of lymph, or fibrine, is called *adhesive*
inflammation ; or the *adhesive stage* of
inflammation.

It is seldom that coagulable lymph *alone*
is thus poured out. Sometimes it is mixed
with the colouring matter of the blood.
Oftener it is mingled with, or at first dis-
solved in, a large quantity of serous fluid.
When this happens in serous bags—as in the
pericardium or pleura—the thinner fluid may
keep the opposite membranes apart ; and for
some time, or entirely, prevent their agglu-
tination. Sometimes the agglutination is
partial, and the uniting portions of lymph
are stretched out, by the distending effect of
the fluid effusion, or by the natural move-
ments of the parts, into strips or bridles of
adhesion.

I must call upon you to notice, in passing,
that although this event of inflammation may

sometimes perhaps have a detrimental or destructive consequence, yet that in a vast majority of instances it is distinctly a salutary and conservative event. Vision may, no doubt, be destroyed by a plug of lymph which shuts up the pupil of the eye. A portion of intestine may become strangulated by a band of adhesion. Of this, which is a mere accident of the adhesion, I have seen some fatal examples. The closure of the trachea by the membrane of croup is not, in my opinion, a fair case in point. There are, at any rate, but few exceptions to the rule, that the effusion of coagulable lymph proves beneficial by preventing some worse event of the inflammation. It is better that inflammation of the cellular tissue should be limited and hemmed in by a barrier of lymph, than that it should extensively diffuse itself. It is better that the bag surrounding the heart, when it happens to be inflamed, should become adherent to that organ, than that the inflammation should run on into suppuration, and fill the pericardium, and oppress the heart, with pus. In the one case life may continue for several years—in the other it seldom lasts many days. It is clearly more desirable, and more consistent with the safety and comfort of the patient, that his lungs should be fastened to his ribs, than that they should be compressed and flattened against his vertebral column. I shall have occasion so frequently to speak of this protecting and reparative tendency of adhesive inflammation, that I do no more than point it out to you at present.

When lymph has been effused upon an inflamed surface, it very readily becomes vascular and *organized.* Red streaks begin to be visible in it. These are incipient blood-vessels, which may soon be seen to communicate freely, and to be continuous with the blood-vessels of the inflamed part. The plastic lymph is fashioned into a definite structure, and made a living constituent portion of the body. It is in truth this remarkable *plastic* property belonging to the effused lymph, this aptitude for being organized, which invests the adhesive inflammation with its guardian and reparative character. None of the other fluids poured out under inflammation are capable of this change. It is in this way that the lips of recent wounds, and the surfaces of inflamed membranes in contact with each other, are permanently stitched together (if I may use so homely a metaphor) by living vascular threads. By this needle-work of nature parts recently severed from the body may sometimes be replaced; or even transferred and affixed to other situations, as in the Taliacotian operation, whereby a new nose is engrafted in the place of that which had been lost. It is thus that ulcers fill up;

successive layers of lymph exude, and are in succession attached to the ulcerated surface, and incorporated by this organizing process, until the breach of texture is repaired. The lymph thus organized comes at last to resemble, very exactly, cellular tissue, more or less condensed. And thus, as I pointed out to you in a former lecture, a texture, identical in its nature with an original texture of the body, is formed as it were *de novo*, and is capable of undergoing the same transformations with the natural texture.

The length of time required for the pouring out of coagulable lymph in inflammation— and for its organization after it has been poured out—is variable under different circumstances. It is often effused very early. Dr. John Thomson found a distinct layer of it covering wounds he had made in an animal, in less than four hours after they had been inflicted; and cases are related, in which vascular organization of the effused lymph has appeared to have been effected within the space of twenty-four or thirty-six hours. Sometimes, on the other hand, many days seem to elapse before any such organization is observable.

When serous fluid and coagulable lymph have been poured out in considerable quantity, and simultaneously, the serous fluid is often rendered turbid by the admixture of small portions of lymph, or of albumen, diffused through it; and *flakes* of lymph sometimes float in it, or settle, in virtue of their specific gravity, at the lowest part of the cavity containing the effused matters.

Several conditions seem necessary to ensure this adhesive form, or adhesive stage, of inflammation. The inflammation must reach a certain degree of intensity, or no lymph will be effused; it must not go beyond a certain degree of intensity, or the next *event* I have to mention, the formation of pus, will interfere with the adhesive process. We learn also from what takes place in recent wounds, that seclusion from the air, and the absence of all other causes of irritation, are necessary for adhesion, or union by the first intention.

Suppuration.—The formation of *pus*— *suppuration*, is a fourth *event of inflammation*, to which brief allusion has already been made.

Many opinions have been broached respecting the nature of pus, and the manner in which it is formed. I shall not trouble you with discussing, or even with narrating them, but limit myself to stating what are the notions held on these points by the most able and the most recent observers.

Pus then, as I told you before, is altered blood. It is an opaque, smooth, yellowish fluid, of the consistence of cream, and having no smell. I speak now of well-formed, or

what is called good, or healthy pus—what he old writers spoke of as *pus laudabile*. This has been thought an absurd epithet: but it serves as well as any other to express what was meant, viz. that kind of pus which accompanies benign forms of inflammation, and indicates that all is going on regularly, and promises a fortunate ending: pus, in short, the appearance of which was *to be commended*. It is certainly not more absurd than the term *healthy* pus. This pus laudabile was described as being *album, læve, et æquale*—light-coloured, smooth, and homogeneous. This description of good pus has descended from the time of Hippocrates, who says Το δε πυον, αριϛον λευκον τε ἐναι, και ὁμαλον, και λειον, και ὡς ἡκιϛα δυσῶδες. It consists of yellowish globules, diffused through a thinner fluid, that resembles in some respects the serum of the blood. " If six or eight ounces of good pus be suffered to stand in a phial, it will separate into two portions: a yellowish matter will sink to the bottom, and there will be a slightly yellow, clear, supernatant fluid, like oil in appearance, but not greasy to the touch." The sediment consists of the globules: there is good reason to believe, with Gendrin, that they are the globules of the blood, altered—deprived of their coloured envelopes, and swollen or enlarged. The changes which they are apt speedily to undergo, from mere exposure to the air, may account for a contrary opinion held by some modern authors.

But there are various modifications of pus; and its qualities are liable to rapid alteration by various circumstances. Sometimes the globules are few in proportion to the more watery part; and then the pus is said to be *ichorous*. It is *sanious* when some of the colouring matter of the blood is poured out with it. It is sometimes viscid and slimy, from an admixture of mucus; or flaky and curdled, which is common in scrofulous persons. Sometimes, also, instead of being inodorous, it is horribly fetid. All abscesses that form in or about the alimentary canal are apt to contain pus of an offensive odour; as those which occur in the tonsils, and near the rectum. A patient of mine, in the hospital, had a fluctuating tumor in the epigastrium, which Mr. Arnott opened. There came out the collapsed bags of two or three hydatids, and a quantity of stinking pus. The liver, no doubt, was the seat of the suppuration in this case—and perhaps the stench might be owing to the death and decomposition of the hydatids.

Great pains have been taken by many persons to discover some sure criterion between pus and mucus. Healthy pus and healthy mucus are so totally unlike each other, that they never can be confounded together. But sometimes we can scarcely say whether we are looking at mucus so

altered as to resemble pus, puriform mucus—or at genuine, though not perhaps laudable, pus. I shall tell you what has been made out upon this point hereafter, when I treat of phthisis; and I shall show you at the same time that the distinction is not of that great importance which has been sometimes supposed.

Pus may be poured out into one of the natural cavities of the body, and then it is called purulent *effusion*. It may be contained in a closed cavity, which is not natural, but formed by lymph and condensed cellular tissue; and then the collection of pus is called an *abscess*. It may also proceed from a free surface of the body—as the skin, or a mucous membrane, or a superficial ulcer or sore.

In the natural cavities of the body pus seems, sometimes, to mingle gradually with the serous effusion, which grows turbid and whitish, and at length distinctly assumes a puriform character. But in much the greater number of cases the formation of pus is preceded by the effusion of coagulable lymph, with or without the effusion of serous fluid: the pus in these cases appears to be poured forth or secreted by the coagulable lymph after it has become organized. Its formation seems to characterize a more advanced stage of inflammation—to denote that the inflammation has been pressed a little beyond the adhesive stage. This was the opinion of John Hunter, who was the first to teach us any thing worth knowing about the process of inflammation. It is also the opinion of Gendrin, one of the latest and most successful investigators of that process. Hunter thus expresses himself on this subject: "the new formed matter peculiar to suppuration is a remove farther from the nature of the blood than the matter formed by adhesive inflammation." And Gendrin says, " Between the *purulent fluid* of inflamed tissues, and the *organizable coagulable* fluid (*i. e.* between pus and coagulable lymph) there is but *one* degree of *more*."

Even the preventing or the allowing the access of air to the surface of a recent cut will make all the difference between adhesion and suppuration. And the same influence of the air in promoting the suppurative process in preference to the adhesive is remarkably seen in various other cases. In simple pleurisy—from exposure to cold—we seldom have any liquids effused, except coagulable lymph, and serous fluid. But if the inflammation has been caused by a punctured wound from without, or by laceration of the *pulmonary* pleura by the sharp end of a fractured rib, or by a perforation of the pulmonary pleura by the extension of a vomica in the lung—in all which cases air finds its way into the cavity of the pleura—then true *empyema* results—pus is formed.

So also in pneumonia : at first the inflamed lung is rendered solid by the effusion of coagulable lymph into the air cells ; but if the inflammation persists, the next thing that happens is what is called by Laennec *grey* hepatization—a puriform infiltration takes the place of the lymph. The same principle is exemplified in the case of the urethra ; inflammation of the *free* surface of its mucous membrane leads rapidly to the formation of pus ; inflammation of its *attached* surface occasions the pouring out of lymph, which produces stricture.   And in general I think it may be said of surfaces that are open to the air, of tegumentary membranes, that either pus is formed upon them, under inflammation, without any previous effusion of plastic lymph, or the lymph is slight in amount, and transient in duration, and presently superseded by a puriform discharge. We have every-day examples of this, in inflammation of the conjunctiva, of the bronchi, and of the bladder. Perhaps it is in this principle that we may find an explanation of the fact that whereas in the inflammation of cellular tissue, of glandular organs, and of the parenchyma of the viscera generally, the pus which forms is collected into an abscess; circumscribed abscess in the substance of the lung, from common inflammation, such as we are now considering, is very rare indeed. This is a point which will of course come under our consideration again.

There is however, manifestly, a close connexion in many cases between the effusion of lymph and the effusion of pus ; although the progress and effects of adhesion and suppuration are very different. When suppuration takes place, the pain belonging to the inflammation usually abates, or ceases, except when the pus is imprisoned so as to keep up the pre-existing tension. Certain remarkable constitutional phenomena also declare themselves, which I shall notice again hereafter.

The effusion is longer continued in the case of suppuration—and the quantity of pus is more copious generally than of lymph —especially in the serous and tegumentary membranes.   When pus is diffused through the natural textures it tends to soften and separate them—to break them down: whereas the direct effect of the deposition of lymph in the same parts is to consolidate and harden.

The time required for the formation of pus is extremely variable. It sometimes very quickly follows the commencement of the inflammation ; within a few hours, as in gonorrhœa. Sometimes it is postponed to a very distant period, even for weeks.

The duration of the suppurative process is also uncertain, and seems to have no fixed relation o the intensity of the inflam-

mation by which it has been preceded or accompanied.

Ulceration—A *fifth event* of *inflammation* is *Ulceration.*   You may remember my telling you that Kaltenbrunner observed the progress of absorption in the inflamed tissues which he examined by the help of the microscope : how the stellated spots gradually vanished from the web of a frog's foot, and the fat from the mesentery of the rabbit.

Independently of these microscopical observations, it is quite evident that absorption goes on, often very actively, during the continuance of inflammation.   The effused fluids, or products of inflammation, the serum, the lymph, the pus, are partly taken up again : and not only are these products of inflammation liable to be so removed, but the original textures of the body are carried off by absorption.   We cannot have a better proof of this than the progress that an abscess makes to the nearest surface at which the pus it contains may be discharged ; the intervening textures are gradually absorbed. Perhaps a great part of the principle concerned in this progressive approach to the surface is *pressure.*   The harder tissues of the body, the bones themselves, yield and disappear before the increasing pressure of an aneurismal tumour.   In this case the absorption appears to be independent of inflammation.

But taking the process as one of the events of inflammation, we may say with Dr. Alison that, whenever the absorption of the effused lymph, and of the surrounding textures, takes place in excess—in a greater degree, that is, and more irregularly than seems to be required for any useful purpose—the result is *ulceration.*   This term is, however, commonly restricted to those cases in which the loss of substance occurs upon some *surface*, internal or external.

Many circumstances influence the occurrence and progress of ulceration ; and great differences are observable in the different tissues, in respect to the facility with which they severally ulcerate.   Ulceration is most common in the tegumentary membranes. It is frequently met with also in the inner coats of the arteries, in cartilages, and in bones.   But we are not always sure that it is in these cases an event of inflammation. Ulceration is rare in fibrous tissues of all kinds, in serous membranes, and in the outer coat of arteries.   These differences have important pathological bearings.   But I may not stop to consider these at present : they will be particularly noticed as the course proceeds.   When I state that ulceration may lead to perforations of the alimentary canal— of the air-tubes—of the gall and urinary bladders—of the blood-vessels ; and to the fatal escape of the natural contents of these organs ; I have said enough to convince you

at ulceration, so frequently the object of
e surgeon's care, requires no less attention
i the part of the physician.

There are certain forms of ulceration that
e specific in their nature : with these I do
ot at present meddle. The process of
ceration is very clearly explained in Dr.
lison's admirable *Outlines of Pathology.*

There are three things generally going on
the same time in an ulcerated surface.
rst, there is an effusion of plastic lymph,
which what are called granulations are
rmed. Granulations consist of coagulable
mph which has become organized;
rnished with numerous delicate blood-
ssels. Secondly, there is suppuration ; and,
irdly, there is absorption or the removal of
rts.

Sometimes, apparently, there is no *suppu-
tion*—we see no pus in ulcers of the cornea,
r in certain cases of absorption of arti-
lar cartilages.

When the first of these three processes
ts the better, if I may so speak, of the
hers, the lymph overspreads the surface of
e ulcer, fills up the cavity, and the ulcer
als : cicatrization takes place.

When, on the other hand, the absorbing
ocess predominates, the ulcer extends
elf—the excavation grows larger, or deeper
or both larger and deeper : and when this
cess of absorption is great, and the exten-
n of the ulceration rapid, it is called *pha-
denic* ulceration. When a part of the
ttures perishes during the process of the ulce-
tion, and is separated in entire and sensible
sses, the ulcer is said to be a *sloughing*
er. " When the process is slow, the
mph effused at the base and round the
ge of the ulcer is hardened, and the granu-
ions on its surface are deficient, the ulcer
then said to be *callous* or indolent : and
en the granulations are larger and softer,
d more flabby than usual, and require to
repressed before the ulcer will heal ; to
s variety of ulcer the name of *fungous*
er is given :" and the coarse and too luxu-
nt granulations are called, by the vulgar,
oud flesh. These several terms, in the
ses now assigned to them, you will please
remember.

It is by regulating the three processes now
scribed—so far as they are capable of being
gulated by art—that the surgeon and the
ysician endeavour to obviate the threatened
consequences of ulceration, and to pro-
te the repair of the textures which have
en destroyed.

I explained to you, in a former lecture, that
lammation may lead to a wasting of parts,
hough there is no suppuration or ulcera-
n. The testis sometimes withers as a
isequence of inflammation : *interstitial*
sorption takes place. *Atrophy* in short.

IN order to aid me in deciding on the best
mode of remedying certain untoward events
that occasionally supervene after the per-
formance of Dieffenbach's operation for the
cure of strabismus, I undertook a series of
experiments on animals for that purpose.
The results of these inquiries, though not so
satisfactory as might be desired, still present
facts of considerable practical importance,
worthy of careful consideration.

In conducting the experiments to be pre-
sently detailed, I may state that I was
favoured, on different occasions, with the
assistance and judgment of Drs. Marshall
Hall and Child, and of Messrs. Samwell and
Farquhar, surgeons, as well as with the
opinions of various non-professional friends,
who, being totally ignorant of the nature of
the investigation, and consequently unpre-
judiced in favour of any cherished theory, or
anticipated results, were the more likely to
take an unbiassed view of the phenomena that
they witnessed, than we ourselves, who, it
may be presumed, could scarcely avoid en-
tertaining preconceived notions.

Before detailing the facts that presented
themselves to our notice, it may be premised
that great difficulty was experienced in
performing the experiments with sufficient
accuracy and care to insure the complete
division of what was required ; and, at the
same time, to confine the operations pre-
cisely within that limit.

All experiments of the operative kind on
the orbital muscles of animals, in order to
ascertain their respective functions, must, on
several accounts, prove more or less unsatis-
factory. The anatomical adaptation of the
powers which move the eyeball in brutes,
differs materially from that observed in the
human species.

In animals there exist certain additional
muscles and appendages to the eye, which
modify the operations of the simple mecha-
nism possessed by them in common with
man. Thus animals are furnished with a
muscle denied to man, the *suspensorius*, by
which they are enabled to retract the eye in
a most remarkable and powerful manner.

The principal object of this muscle seems
to be to assist in retaining the eyeball *in situ*,
and to obviate any inconvenience, or bad
consequences, that might result from the

long-continued dependent position of the head, during the time that the animal is feeding, which, in the *Ruminants*, engages so considerable a portion of the twenty-four hours.

In this class of animals, therefore, we find the suspensorius muscle not only powerful, but very large and funnel-shaped, so as to completely and uninterruptedly embrace the posterior half of the eyeball, and thus most effectually to accomplish this apparently important end. In *carnivorous* animals, whose time is not so much occupied in feeding, and whose heads, therefore, are not so constantly in a depending position, the suspensorius muscle is not so powerful or comprehensive. On the contrary, it is divided into distinct parts, forming, in fact, four independent fleshy slips, which have a common origin, but are inserted into the sclerotis by separate tendons reaching to the greatest transverse diameter of the eyeball, and passing between the attachments of the four principal recti muscles. The oblique muscles also, in ruminating and carnivorous animals, differ from each other in many respects. In the latter class, and in man, the *superior* oblique becomes tendinous immediately before it reaches the pulley affixed to the orbital angle of the frontal bone, and continues its tendinous form, from this point of reflection, to that of insertion into the sclerotic coat : whereas, in ruminants, the reflected portion of this muscle forms a second fleshy belly of considerable thickness and power, which again becomes tendinous before its final insertion. The part of the eyeball into which this muscle is inserted does not precisely correspond with the same portion in man ; the insertion of the tendon being a little nearer to the cornea than in animals. The *inferior* oblique likewise, in animals, is a much stronger, more fleshy, and abrupt muscle, than it is in man, in whom its insertion is much more extensive, and effected by means of a stronger and more spreading tendon.

When any attempt is made to injure the eye of an animal, the suspensorius, or more properly the *retrahens* muscle, immediately draws the eye back into the orbit ; and, in doing so, still further protects the organ, by causing the immediate and forcible advance of the membrana nictitans, which unfolds and spreads itself like a curtain over the fore part of the eye.

In experimenting on the internal rectus and oblique muscles in particular, this membrane is a source of great difficulty and embarrassment to the operator, as it not only comes constantly in the way of his instruments, but prevents the observer, after the desired end may have been accomplished, from ascertaining the precise direction in which the pupil is drawn, when the eyeball performs any rapid or involuntary movement, such as may result from slightly irritating the cornea with a feather, or the like.

In all the movements of the eye, indeed, that are not voluntary on the part of the animal, difficulty is experienced in making allowance for the influence of this suspensorius, as any portion of it appears to be capable of being called into play, to the exclusion of the rest of the muscle, especially in animals of the carnivorous tribe, in which, as just explained, it is divided into four distinct auxiliary recti muscles. Thus, if the adductor draw the pupil towards the nasal canthus of the orbit, and the inner portion of the suspensorius or retrahens co-operate with it, the effect is much heightened by the inner portion of the eyeball being at the same time drawn back towards the origin of this auxiliary muscle ; and the same is the case when any of the other three recti are forced into involuntary action. Could a series of experiments be performed on any of the ape tribe, the orbital muscles of which class of animals resemble in every particular those of the human species, we might possibly arrive at better and more satisfactory conclusions. But even then we should have to contend with another difficulty, that equally opposes our inquiries when experimenting on a class of animals inferior to this, viz. the want of that intelligence which distinguishes reasoning beings.

We cannot, of course, when a muscle is divided in a brute creature, estimate the result in all its bearings, as in man, by requiring the animal to move in such directions as would aid our judgment, and satisfy us that specific results have been obtained, and certain objects accomplished. On the contrary, the only conclusions we can arrive at must be deduced from a comparison of the movements of the two eyes, when, by stratagem, we can excite the natural contractions of certain muscles in the organ that has not been the subject of operation. If, on inducing special movements in the sound eye, we find that those of the other organs do not correspond, we may fairly conclude, if they were previously complete, that the power of producing them has been destroyed.

Notwithstanding all these obstacles, however, a few plain and incontrovertible facts do present themselves, which are of sufficient practical utility to merit careful consideration.

The first experiments that I shall relate were instituted with a view to ascertain the results of dividing the several recti muscles. And, it may afford a tolerable criterion of the results we might expect to occur, were the corresponding tendons divided in the

human species; provided the muscles were in a healthy condition, and the eye not in any way affected with strabismus.

Exp. I.—*Division of the Internal Rectus.*

The tendon of the adductor of the left eye of a middle-sized half-bred spaniel dog, was carefully separated from its attachment to the sclerotis. The pupil was instantly directed permanently towards the outer angle of the orbit; and to such an extent that, next day, fully one-third of the cornea was concealed from view. The animal appeared to be wholly incapable of disengaging the pupil from this situation; nor did he acquire the power of doing so in the slightest degree afterwards.

Exp. II.—*Division of the External Rectus of the same Eye.*

In the course of a week from the performance of the operation, the *external* rectus of the same eye was divided, but without producing any sensible alteration in the position of the eyeball: the pupil still continued to be everted, and partially concealed in the temporal angle of the orbit.

From these facts we may conclude, either that the muscle had not formed a re-union with the sclerotic coat, or that, the eyeball having been so long unremittingly turned outwards, the re-union was established too far posterior to the original insertion to enable the muscle to invert the pupil again.

Exp. III.—*Division of the External Rectus Muscle alone.*

The abductor of the left eye of another dog, similar in size to the last, being carefully divided, the pupil was permanently turned inwards towards the nasal canthus of the orbit, *but not quite in so great a degree as, in the first experiment, it was turned outwards.* Nor did the animal, in this instance, apparently possess any power to dislodge it from its unnatural situation. This we ascertained, in both experiments, by holding its head in a particular position, and then calling the attention of the animal to the opposite direction. On such occasions the intact eye alone obeyed the summons of the will; the other did not move in unison with it.

From the three foregoing experiments, which were afterwards several times repeated, and farther verified in the course of operating on other animals, we may infer—

That, when all the orbital muscles are in a *sound* and *healthy* condition, if we divide either the adductor or abductor, the natural tendency of the antagonist muscle is to contract in the fullest degree of which it is capable; and that, in doing so, it will produce a deformity of the eye similar to that which characterizes ordinary internal or external strabismus;* with this difference, that the movements of the eyeball in the direction of the cut muscle will be wholly destroyed. When, however, we divide the adductor in the human eye, for the purpose of remedying strabismus, we very rarely find that the pupil is drawn outwards beyond the visual axis of the orbit. Hence we may conclude, that, under such circumstances, the eyeball is either prevented from turning outwards by some retaining adventitious cause, independent of the contracted adductor, which, after its section, no longer offers any opposition, or that the external rectus has been previously partially paralysed, as supposed by Mr. C. Guthrie (vide his Report). These facts, moreover, point out the propriety of not only satisfactorily ascertaining that the eye is affected with *confirmed* strabismus previous to operating, but, at the same time, warn us of the troublesome, if not unfortunate, consequences that may possibly result from immediately dividing the adductor tendon in the second eye, *when not in any way implicated*, as proposed and practised by Mr. Elliot, of Carlisle, should the section of the tendon of the faulty organ not prove *instantly* and *completely* successful.†

Another inference to be deduced from the foregoing fact is, that the oblique muscles take very little part in the lateral movements of the eyes.

When the internal rectus was divided, the obliques did not enable the animal to approximate the pupil at all to the nasal canthus of the orbit; neither did they, on the other hand, contribute the power of everting the pupil, when the external rectus was divided, unless in a very trifling degree; since it will be observed, by reference to the third experiment, that the pupil was not proportionally so much *inverted* when the external rectus was detached, as it was *everted* on the division of the internal muscle. This difference in the degree of displacement of the pupil may have been attributable to the combined action of the two obliques, if their actions be in any way calculated to aid that of the external rectus, as was supposed by Albinus, and is still maintained by Sir Charles Bell, Dr. Marshall Hall, and others. The power, therefore, that many patients possess of turning the pupils slightly inwards after the adductor muscle is divided, we may presume to be dependent much more on the

* This experiment, though performed a week afterwards, is detailed here, as being connected with the former one.

* If this result be the general law when the orbital muscles are divided, while in a healthy condition, then some of the arguments adduced, in a former article, to explain the reason why the pupil does not usually turn outwards after the operation for convergent strabismus, fall to the ground.

† Vide Lancet, Oct. 31, 1840.

acquired influence of the inner fibres of the superior and inferior recti, than on the action of the oblique muscles. Hence, also, another argument in proof of the doctrine, which I have already advanced, that division of either of these latter muscles can never be requisite in the cure of convergent strabismus.

But a practical question of much importance suggests itself for our consideration in reflecting on the foregoing facts, viz. When the pupil is very much everted on dividing the internal rectus—so much so, I mean, that we are satisfied time will not rectify the position the eye has assumed—ought we to wait, before cutting the tendon of the abductor, until re-union shall have taken place between that of its antagonist and the sclerotis, or ought we at once to perform this second operation ?

When such an event takes place, *i. e.* when the pupil is everted in a remarkable degree, I apprehend that the case is one in which the strabismus had been primitively produced by *spasm* of the inner rectus ; and that the external muscle, being in a healthy condition, was capable of its fullest degree of contraction. Were we to wait in such case, it is possible that the abductor might form a re-union too far back to be able to restore the pupil to the axis of the orbit, when the abductor tendon should be afterwards separated. If, on the other hand, we do not wait, we have seen that the eye will, in all probability, not be restored to its normal position, while both muscles are equally incapable of action, but that it will retain the position in which it is placed by the first operation. This *permanent* state of eversion, however, is a circumstance that, it would seem, does not occur in the human eye under the circumstances we are considering. However much the external rectus may contract after the abductor has been cut across, in a *strabismal* eye, the patient always possesses the power, when the eye is used *in conjunction with its fellow*, of bringing it to the central point between the inner and outer angle of the orbit, although at such moments the axes of the two eyes do not correspond, and vision is consequently double. If, however, a case were to present itself in which the pupil should be permanently turned outwards after the division of the abductor tendon, and the patient did not possess the power of removing it from this position, it occurs to me that we should gain nothing by waiting until the inner tendon was re-united, and that it would be better to divide the outer muscle at once. It is possible in such case, were the eye liberated, that the superior and inferior muscles might rectify the morbid position of the pupil. A case parallel to that just supposed, it will presently be shown,

has actually occurred with regard to the superior rectus in the human eye.

From the foregoing experiments we should naturally expect that similar phenomena would attend the division of the superior and inferior recti ; but such is not the case.

Exp. IV.—*Division of the Inferior Rectus.*

In this instance the tendon of the inferior rectus was separated with great care :* the animal lost completely all power of directing the pupil downwards, when that of the other eye was depressed ; but it was not drawn upwards, as was expected, by the action of the superior rectus. Three days afterwards, however, it was found to be displaced in this direction, the upper third of the cornea being concealed under the superior palpebra, which situation it continued to occupy.

Exp. V.—*Division of the Superior Rectus.*

The superior rectus of the left eye of a middle-sized dog was separated from its insertion ; the position of the pupil was not altered, although it appeared that the animal could not direct the eye upwards.

Exp. VI. — *Division of the Inferior, Internal, and Superior Recti.*

This experiment, as will be immediately shown, was performed for a special purpose. The inferior rectus was first detached, then the abductor, and finally the superior muscle. The pupil at first preserved its natural central position, but in the course of two days afterwards was found to be directed outwards, and very slightly upwards.

My object in performing this experiment was to ascertain whether, when the internal rectus has been divided to remedy strabismus, and the pupil is drawn upwards under the superior palpebra in consequence of the deformity having arisen from *paralysis* of the *inferior* rectus, any benefit would be derived from dividing the superior muscle. From the result of the experiment, and the experience of two cases of this description which I have met with, it appears to me that the operation would be useful *after the abductor tendon has become re-united to the eyeball.*

Exp. VII.—*Division of all the Straight Muscles.*

In this experiment all the straight muscles were detached : the pupil remained fixed in the visual axis of the orbit. When irritated, the eyeball was retracted, and the membrana nictitans was suddenly spread over the fore part of the eye at the same

* These dogs were in general afterwards killed, within an hour or two, and care was always taken to ascertain that the proposed object had been accomplished.

moment, so that it was quite impossible to decide what influence the oblique muscles exerted, or whether they produced any special movement at all. It was clear, however, that they neither drew the eye towards the outer nor the inner angle of the orbit. Hence I am disposed to imagine, as already stated, that when both of these muscles contract together, they tend to steady the eyeball in the visual axis of the orbit, and contribute to modify the focus of the eye by compressing the sphere. They are, in such case, opponents, though in a slight degree, of the external rectus.

Exp. VIII. — *Division of the Superior Oblique and Internal Rectus Muscles.*

The greatest difficulty was experienced in performing this operation satisfactorily, in consequence of the retraction of the eyeball, and the protrusion of the membrana nictitans. A sharp-pointed bistoury was introduced at a right angle to the tendon, and about midway between the trochlea affixed to the frontal bone, and the insertion of the muscle into the sclerotis. The instrument was pushed sufficiently deep into the orbit to secure the cutting of the tendon on its being withdrawn with the point in contact with the roof of the orbit. There could, therefore, be no doubt that the tendon was divided. No apparent change occurred in the position of the pupil; nor could we perceive that the movements of the eyeball were in any way modified, or destroyed, by the operation.

The insertion of the internal rectus of the same eye was next separated from the sclerotis, and instantly the eyeball *protruded considerably*, and the pupil—dilated in a most extraordinary manner* — was drawn diagonally outwards and upwards, as if by the equal co-operation of the outer fibres of the superior rectus, and the upper fibres of the external, or abducens, muscle. The eyeball afterwards retained this position, and, when the muscles were sympathetically irritated to involuntary contraction, by gently touching the cornea, was always re-

* Slight temporary dilatation of the pupil often supervenes in the ordinary operation for strabismus, on dividing the internal rectus, especially in those cases in which the eyeball becomes somewhat more prominent immediately after the operation. But, when, in an animal, either of the oblique muscles is cut across, the enlargement of the muscles is very considerable. The iris contracts into a fine circular band, not above half a line or a line in breadth, and the eye presents an appearance very similar to that produced when the animal is poisoned with prussic acid. We should naturally imagine, as the pupil dilates when the eyeball is compressed, and contracts again when the pressure is withdrawn, that liberating the sphere, by cutting a portion of its attachments, would give rise to contraction; but the contrary is the invariable result. It may be presumed, then, that when the eye protrudes, the remaining recti muscles, being stretched, compress the sides of the globe.

tracted by the action of the retrahens. On such occasions, the upper and outer portion of the sphere appeared to be the part most retracted; the lower and inner portion being at the same moment made to advance obliquely, and project in a remarkable manner.

Exp. IX.—*Division of the Internal Rectus and Superior Oblique Muscles.*

In the ninth experiment the foregoing operations were reversed on another dog: the section of the internal rectus was first performed, then that of the superior oblique muscle. The results were similar to those just related. The eyeball was directed outwards and upwards; its anterior inferior surface was brought into view, and considerable protrusion took place, accompanied with remarkable dilatation of the pupil. When the internal rectus alone was divided in this experiment, as in No. 1, the pupil was turned directly outwards; but, when the superior oblique was cut across, its direction was found to be outwards and upwards. This diagonal direction of the pupil, then, in the two last experiments, although such as might be presumed would be produced by the equal co-operation of the external and superior recti muscles, I am inclined to attribute, in a great measure, to the uncounteracted action of the inferior oblique, since it was exactly what might have been anticipated from the direction of the fibres of this muscle, and did not become *diagonal* until the section of the superior oblique had been performed. Be this as it may, the other result, viz. great projection of the lower portion of the eyeball, so that the anterior part of its under surface was brought into view on slightly depressing the lower eyelid, could be attributed to no other cause than the contraction of this muscle when unopposed by the trochlear.

Exp. X. and XI.—*Division of the Inferior Oblique and Internal Rectus Muscles.*

These experiments were conducted in a similar manner to the two last related, and the section of the former muscle, the inferior oblique, was accomplished on the same principle as had been that of the superior oblique; the bistoury being withdrawn with its point in contact with the floor of the orbit. The results which succeeded were very similar to those we had already witnessed. The eyeball protruded as soon as the adductor was cut across, but not before; neither did it project in so great a degree as in the former experiments. The pupil was directed outwards, but not upwards; and in this situation it remained immoveably fixed.

Most of the foregoing experiments I have repeated several times, and uniformly with

the same results; the degree in which they manifest themselves, however, being various in different animals.

On one occasion, when assisted by Mr. Samwell, on dividing the superior oblique, the pupil was drawn so forcibly towards the outer canthus by the action of the external and superior recti muscles, that, had it not apparently been for the restraining power exerted by the inferior rectus on the lower portion of the eyeball, it would have wholly disappeared.

What, then, are the functions of the superior oblique muscles? So far as may be inferred from the foregoing experiments, very little of a conclusive nature can be deduced.

It certainly appears somewhat paradoxical, and irreconcileable with a first view of the subject, that dividing one of two muscular powers, which both tend, though perhaps in different degrees, to bring the eyeball forwards in the orbit, should be a means of causing it to advance still more, even to protrusion; yet such would appear to be the fact. If we reflect on the course and insertions of these two muscles, we shall perceive that, when they act singly, it is probable they antagonize each other in the *semi-rotatory* movements of the eyeball; and that when they contract at the same time, they will co-operate in drawing the eyeball forwards in the orbit, but *without causing it to revolve in any direction*. On the contrary, they will steady it; and, as the origin of both of these muscles is from the nasal side of the orbit, they will fix the globe of the eye in the visual axis when we look steadfastly at an object placed immediately before us, and at the distance from the eye at which we can see it the most distinctly; *i. e.* at the true focus of the organ—this being the position in which the exertion of a steadying power is of the most importance, and that which is the most frequently exercised of any. If, moreover, the focus of the eye be ever changed, so as to suit it to the various distances at which we survey objects, these muscles, it appears to me, may be very powerful agents in accomplishing this purpose, by compressing the central portion of the sphere slightly between them, and against the cushion of fat which lines the nasal surface of the orbit; thus not only increasing the distance between the cornea and that portion of the retina on which the image is depicted, but also rendering the cornea itself more convex. The importance of steadying the eye, under particular circumstances, against any inadvertent contraction of the recti, and of accommodating its focus to view objects at various distances, is too obvious to need any comment; and I think we shall, on reflection, be inclined to admit that the same end could not be so efficiently

attained by any combination of agency on the part of the recti muscles. When the trochlear muscle contracts, and the inferior oblique is relaxed, it appears to me that the effect will be to slightly rotate the eyeball downwards and inwards; and that when the lower muscle contracts, the upper one being at the same time relaxed, the effect will be to cause the eyeball to slightly revolve inwards, *i. e.* towards the nasal canthus, and upwards.

But we have seen that there was reason to believe that the inferior oblique aided the external rectus—a view that was taken of its actions by Albinus, and is still maintained by Sir Charles Bell, Dr. Marshall Hall, and others. Certainly, if we consider the direction of its fibres, and the extreme point of their expanded insertion, reaching nearly to the optic nerve, we can scarcely avoid arriving at this conclusion also—viz. that when left free to contract, as it especially is, if the tendon of its antagonist be divided, it will direct the pupil outwards and upwards, and thus assist the external rectus. But not so the superior oblique; at least certainly not in so great a degree. Its insertion, which is by a round tendon, does not usually extend more than two lines beyond the central diameter of the sphere*; neither does it, in so great a degree, transversely embrace its circumference. To me it appears probable that this muscle, *when both obliques are entire*, can only assist the *internal* rectus, while the inferior one may aid the *external* muscle in certain compound movements of the eye, the nature of which we at present know little or nothing about.

But there is a practical inference to be deduced from the foregoing facts, of considerable importance.

If the eyeball be protruded in the manner we have seen it may be, when either of th oblique muscles is divided in animals furnished with a suspensorius or retractin-muscle, how much more might we fear it would be so, were the same operation practised on man, to whom this muscle is denied.

Presuming this extension of the operation to have been attempted with impunity, it appears to me unnecessary to offer any comment on the propriety of farther inquiry before it be repeated.

14, Langham Place, Regent-st.
Nov. 19, 1840.

* In most works on anatomy we are informed that the insertion of the trochlearis does not extend beyond the great diameter of the eye. But this, it would appear, is not correct. I have of late dissected a number of eyes for the purpose of ascertaining this fact, and have, in every instance, found the insertion to be posterior to the greatest diameter of the eyeball. In a preparation now in my possession, the ultimate fibres of the tendon were inserted more than three-eighths of an inch posterior to the central diameter of the sphere.

SITUATION OF THE PLACENTA.

To the Editor of the Medical Gazette.

Sir,

An attempt having been made in the number of your periodical for the 3d instant to impugn a statistical table, indicating the situation of the placenta in 100 cases, published by me in the Dublin Journal of Medical Science for March last, I trust you will permit me to offer a few observations in support of the data on which that table was constructed. And firstly, I would briefly allude to the circumstances to which it owes its origin.

Mr. Hugh Carmichael, of this city, having laid before the profession, in the Dublin Journal for January, 1839, certain novel views with respect to the mode of growth and contractions of the womb, which appeared to me as interesting as they were new, I determined in every way in my power to test their correctness. For this purpose I attentively examined the arguments upon which his theory was founded, and endeavoured, by the observation of cases, which I considered bore upon the question, to come to a just conclusion. The result of my inquiry was, that I collected several cases completely opposed to his doctrine, and in the same periodical I advanced them as incompatible therewith. To the cases thus brought forward Mr. Carmichael afterwards took exceptions, in consequence of which I again applied myself to the subject, and extended my observations to a hundred others, which I found still to bear so strongly against the positions he laid down, that I again inserted in the Dublin Journal the fruits of my investigation. The conclusions arrived at that gentleman has now, in your publication, endeavoured to overturn. I shall therefore, with your permission, enter once more, with as much brevity as possible, into the question at issue.

The theory Mr. Carmichael has advanced is, that the growth of the uterus during gestation, instead of taking place, as now believed, by a general enlargement in all directions, is confined to one part alone, its anterior segment; which, increasing in altitude, occupies and passes over the fundus layer after layer, until the expansion has arrived at its maximum. At that time he considers that all that portion of the back of the womb above the Fallopian tubes, the entire fundus, and the anterior wall, have been supplied from the increase of the latter part alone, and that the posterior wall below the tubes has undergone little alteration from its condition in the unimpregnated state.

The arguments upon which he founded this opinion were threefold. Firstly, he maintained that the growth of the fundus is too great to permit the placenta, if it continued in the upper region of the uterus, to keep pace with it in development; in confirmation of which position he referred to several instances where he considered hæmorrhage owed its origin to the fact alone of the placenta being situated, at the time of labour, too high on the posterior wall. He does not appear ever to have met with a case in which it held an anterior position, nor one in which it adhered to the fundus; but of the latter he expressed his conviction, that so incompatible was it with his views, such an arrangement could not but give rise to separation of the placental and uterine surfaces, and its consequences. Secondly, he stated that in examining many cases, he always found, in natural ones, the placenta to have adhered low down on the posterior wall at the termination of gestation, although it is an admitted fact the ovum forms its first attachment to the fundus, or very close to it. And thirdly, he considered that the change which the Fallopian tubes undergo during the enlargement of the uterus, being at the full time not only much removed from the fundus, but also, having then a posterior aspect, demonstrated the whole growth of the organ to have been anteriorly.

Upon this basis he rested his doctrine that the anterior wall expanded in the way I have mentioned; the contractions he considered to take place exactly in a reverse direction, and be confined to the anterior wall until after the expulsion of the child, at which time he believed them to extend to the lower part of the posterior wall also, and so to detach the placenta. By this means he is of opinion nature has provided for the security of the latter important organ, placing it out of the reach of alterations in the capacity of the womb, until it becomes itself useless,

and protecting it against the consequences which must have ensued, were it exposed to the vicissitudes attending them.

Against these positions I argued as follows :—If it be a fact, that the growth of the fundus is so great that the placenta could not maintain with it an equality of development, hemorrhage must, in every instance, result, when the afterbirth is found at the period of labour either wholly or in part within the upper segment of the organ ; and if this be the case with the fundus, it must be much more so with the anterior wall, supposing its expansion to take place so extensively as described. It appeared to me, therefore, that if I instanced cases which exemplified the placenta, first high up on the posterior wall, secondly attached to the fundus, and thirdly attached anteriorly,—cases in which no untoward occurrence happened to either mother or child,—I would hence demonstrate his theory to be built on an unstable foundation. This I accordingly did. At the same time, I pointed out the circumstances which, in my mind, influenced the seat of the placenta. I observed that the height at which the ovum attaches itself, must depend, in a great degree, on the decidua reflexa ; if that membrane be rapid in its growth, or easily prolonged, the ovum of course arrives at a lower part of the uterus before it forms its union with the maternal structures, than where the reflexa is of opposite qualities — a fact which is proved by the inspection of abortions, the cord obviously springing in different specimens at a higher or lower elevation. The evidence thus obtainable, too, is quite at variance with Mr. Carmichael's statement, that the ovum invariably forms its first adhesion on the fundus, or close to it. I also noticed the possibility that the wall on which the placenta forms, depends, firstly, on the position of the uterus at the time, and secondly, on the quantity of the fluid its cavity then contains. In the usual condition of the parts, the uterus placed obliquely, the fundus leaning forward, the hydroperione must float the ovum, contained in the reflexa in contact with the upper portion of the posterior wall ; and accordingly there the ovum in a large proportion of instances attaches itself. But if the quantity of

decidual fluid be not sufficient to support the reflexa in the manner described, its gravity carries it towards the anterior wall, and there the placenta is formed. It is probable also, that if the uterus presents a less degree of obliquity, or leans to one or either side, the reflexa will be elevated by the hydroperione to that which is uppermost, and there the union will be accomplished.

These observations may or may not be true, but at all events I think I have shewn, in the paper I allude to, that on whatever part the placenta forms, there it remains and grows, and there it will in all stages of gestation be found ; and any slight deviations are sufficiently explained by the inequality of its own development, which the frequent deviation of the cord from the central point demonstrates a not unusual occurrence. With respect to the Fallopian tubes, I quoted a passage from Dewees, which, I repeat, will be found at page 88 of his treatise, in which he stated that the enlargement of the uterus is confined almost entirely to the *posterior* segment, and that at the termination of pregnancy the tubes are situated *anteriorly*. This passage Mr. Carmichael declares he has not been able to find ; the fact he denies. But if he will only pass a line around the gravid uterus at the full time, where the tubes penetrate its substance, he will find three-fifths situated posteriorly to them, and two-fifths anteriorly. This observation I had from Dr. Montgomery, whose accuracy on such a subject no man will question ; its correctness I have verified by reference to casts and preparations in his museum.

To the cases I have brought forward the author replied, that as in all of them some circumstance arose to call for interference, not one could be considered natural, and, consequently, no argument could be founded on them. I certainly admit there is some force in the observation, that where considerable bony deformity exists, the placenta may have assumed an unusual position, but I conceive its situation could not possibly be influenced by a deposition of osseous or other matter upon it sufficient to cause morbid adhesion. This is a process which takes place *after* its formation, often in the very last days of pregnancy, and could not surely cause it to shift its adhesions. His

argument, too, that no deduction should be drawn from the evidence afforded by the introduction of the hand after the expulsion of the child, because the process of contraction he has described would then produce a change in the situation of the mass, appears to me to be begging the question ; it is assuming that which has not been proved, viz. the action of the anterior wall independent of the posterior. For these reasons, I felt, and still feel, that all my original cases, except those where deformity existed, were proper materials in deciding the question at issue. But as they had not satisfied the author, I determined to follow, as closely as possible, the mode he pointed out for ascertaining the seat of the placenta.

This method consists of two parts ; firstly, the application of the stethoscope, and secondly, the inspection of the secundines after they were expelled. With respect to the former, the author stated, in contradiction of every writer on the subject, that the bruit being always heard in one or other iliac fossa alone, testified that the placenta was always attached where he represented. The evidence to be deduced from the secundines he gives in the following terms :—

"The child before birth is enveloped in a double cyst of membranes, proper to itself, independent of one formed by the womb at conception. These membranes, though unattached to the uterus, are firmly united to the placenta and cord, and do not come away in labour except with the latter. It is obvious, then, that in order to birth, the child must perforate the cyst, and thus form an aperture therein : now, if care be taken in the delivery of these parts, that the membranes shall be preserved unbroken except at the place through which the child escapes, the information we require may be obtained with the utmost correctness : for example, if the borders of the aperture be equidistant from the placenta in all directions, then this latter must have been exactly opposite, and consequently at the fundus, for the aperture is obviously at its mouth ; but if, on the contrary, the distance be considerable in one direction, while it is but very little removed from the placenta in the other, then it is evident that the fundus was not the position it occupied, but somewhere not far from the mouth of the

womb; in fact, by inflating the membranes so preserved, we have an exact representation of how they and the placenta were situated in utero."— *Dub. Journ* for Jan. 1839, p. 462.

This is all very good so far as it goes, but it is by no means a modern observation, the same having been known to Smellie, who makes use of it as Mr. Carmichael has done, nearly a century after, to combat an opinion then entertained, but since well known to be erroneous, that the placenta is usually attached to the fundus. "When the placenta is delivered," says Smellie, in the 3d chapter and 9th section of his Treatise, "and no other part of the membranes torn except that through which the child passed, the opening is generally near the edge or side of the placenta, and seldom in the middle of the membranes ; and a hog's bladder being introduced at this opening, and inflated when lying in water, will shew the shape and size of the inner surface of the womb, and plainly discover the part to which the placenta adhered."

Now it must be evident, that, though in either of these ways it can be made apparent whether or not the placenta adhered to the fundus, it cannot be distinguished on which wall it had been implanted. This did not escape Mr. Carmichael, who thus continues :— "By introducing the hand into the opening, we get into a pouch formed by the membranes, the superior part of which evidently corresponded with the fundus; and then, by running the finger along their inside, opposite to where they are attached to the placenta, we are at once enabled to perceive, by their peculiar appearance there, that at that part they lined the anterior distended and convex portion of the womb, and thus, consequently, fix the back part of it to be the place where the placenta was attached."

Such are the directions Mr. Carmichael gives for ascertaining this point; but I am sure such a mode will not satisfy any mind but his own. Will it suffice to introduce the hand, and, running the finger along the membrane, thus guess at which was a concave and which a convex portion? In so flexible a material, I ask, cannot any portion be made by pressure to appear more or less prominent? And is not such a mode of investigation most futile and deceptive? It is founded, too, on the

supposition that the anterior part of the uterus is much more rounded, even at its inner surface, than the posterior—a fact which Dewees denies, and which the actual position of the Fallopian tubes on the anterior aspect tends to disprove. If there be any difference in this respect, it can never be so great as would be indicated in the way mentioned.

Convinced, then, that this method was uncertain, and yet feeling satisfied the secundines could afford the evidence required, I turned my thoughts to the subject ; and, on reflection, it appeared to me evident we had only to observe the way in which their separation and expulsion are accomplished, to acquire the information we stood in need of. This process I thus described in the Dublin Journal for March last, p. 20 :—

"The evidence afforded by the secundines is founded on the fact of the placenta, in the majority of instances, being expelled with the membranes reversed, and its fœtal surface downwards. When this is the case, it is obvious the upper edge must in its separation have been momentarily earlier than the lower, and thrown towards the wall opposite that on which the mass was implanted—a direction the membranes, which usually remain longer adherent, tend still further to give it. But as the membranes arising from the upper edge pass over the fundus and down the opposite wall to the os tincæ, they must be much longer than at the inferior edge, and the length of the latter will shew how far from the os the placenta was actually situated. As this, however, will not be sufficient to tell us to what wall it was appended, I adopt the expedient of inserting a pin, as it lies on the bed fully expelled, into the margin close to the patient's thigh. Thus I am able to distinguish the anterior from the posterior part when removed for examination. Recollecting now that the upper edge is thrown (falls would better express my meaning) towards the opposite wall, it must be evident, if the long membrane be found at the pubal margin, the placenta must have been on the posterior wall ; if at the perineal, on the anterior. The same will hold good with respect to the lateral parietes. But frequently the membranes being early detached, come down in their natural relation, unreversed, or only one-half inverted ;

still I have satisfied myself the separation of the placenta, in by far the greatest proportion of cases, takes place from above downwards, which indeed is proved by the fact that the fœtal surface is still the first to make its appearance. In a very few the uterine surface is first seen, and then it follows, the secundines will tell an exactly opposite tale to what they ought. For instance, if the placenta be on the posterior wall, and the lower edge is first or simultaneously detached, it may be directed by the perineum towards the pubis, and the short membrane will then be there found when it is expelled. This error, however, can easily be guarded against, by watching which surface descends foremost, or, in other words, which remains directed towards the vulva; indeed, it is principally, I might almost say only, when it has been on the posterior wall, and, consequently, had the perineum to slide along, I have observed it so detruded."

To these observations Mr. Carmichael has made, in the MEDICAL GAZETTE, the following objections : – " Although the earlier detachment of the superior portion of the placenta is stated in the critique as quite obvious, I by no means assent to the postulate. I have laid grounds in my paper for supposing that uterine contraction is very much conducted on the anterior wall of the womb until the child is expelled ; and if that be the case, I cannot see how such a mode of detachment is so obvious ;" (I think we could not find a better specimen of that mode of arguing commonly called "begging the question," than this passage; however, the author continues,) "on the contrary, I should think the entire of the placenta-uterine surface would be acted on at once; indeed, I think this must be ·so, no matter how the contractions be ; in which opinion I am strengthened by the well-known fatal consequences resulting from partial detachment. But admitting the superior portion to be first detached, by what means is it alone thrown to the opposite wall of the womb? Again, supposing all these granted, I contend the capacity of the womb is by no means such as to admit the advance of the superior section of the placenta to take place to such a degree as to permit the mass to assume the position necessary to sustain this argument."

Now in the foregoing remarks I

think I need scarcely say I have been throughout his whole work entirely misunderstood. I by no means intended to convey, that the superior portion of the placenta is detached any considerable time before the superior ; my words were, " momentarily earlier ;" and I believe that the contractions of the uterus, occurring from above downwards, must have that effect ; nor did I imagine the placenta, in its transit through the uterus, assumed "an antero-posterior or horizontal position," and, as if it were made of tin (but even that would bend under uterine action), required a space equal to its breadth, when spread out, to permit it to pass. On such a supposition it was very easy to talk of hæmorrhage, which should occur ; but, unfortunately for the applicability of such observations, my description of the birth of the secundines supposes it to be produced by active uterine contraction.

To make that description plainer, I shall offer the following additional explanation : — It is universally admitted, in the great majority of instances, the placenta is expelled with its fœtal surface downwards, the membranes being reversed, and following in its train. That being the case, we shall suppose the placenta to adhere to the posterior wall of the uterus, and the child to have passed through an opening made in the transparent membranes at the part corresponding to the os tincæ. It must be evident that, situated as the placenta is at present, it has dependent from its inferior margin a portion of membrane, which is but short, as it merely passes downward as far as the mouth of the womb ; while from its superior border the membrane proceeds upwards, and lining the fundus, descends along the anterior wall to the corresponding lip of the os ; and that the latter must, therefore, be much longer than the former. When uterine action recurs, the placenta is detached. I believe, from above downwards, but we shall say simultaneously throughout its whole extent ; but the membranes are not separated at the same time. The weight of the placenta, then, increased by blood extravasated on its uterine surface, causes it to sink towards the os, but of course folded up by the uterine compression ; and it must be apparent, when we recollect that its fœtal surface comes fore-

most, that in doing so its upper margin sweeps along the anterior wall of the uterus : in no other way can it come down with its fœtal surface presenting. The placenta being now situated in the upper strait of the pelvis, if the finger be introduced it will reach the insertion of the cord : the short membrane has probably separated itself entirely from the womb, and of course maintains a posterior position, but the long membrane forms a double upon itself, as can be ascertained by passing the hand, and the external layer of that double still retains its adhesions to the anterior wall, while the internal layer (that which covered the posterior wall above the placenta and the fundus) is free on its surfaces, but continuous above with the external layer, and below with that part of the afterbirth, which was its superior edge, but is now the anterior. When the process goes still further, and the placenta advances to the vulva, first is seen the root of the cord spreading its large vessels over the fœtal surface ; then out comes the whole mass, the posterior edge hurrying with it the short membrane, the anterior at its exit evidently peeling off the last adhesions of the long membrane. Sometimes the latter are not thus overcome, and then the finger, passed along the pubis, detects the membrane not yet detached from the anterior part and sides of the uterine neck, and by proper manipulation separates it. The reverse of all this will hold good when the placenta occupies the anterior wall, the superior edge, with its long membrane, passing in its exit along the posterior wall of the uterus and vagina, and ultimately escaping at the perineal extremity of the genital fissure.

It must be evident from this description, which any one who has paid attention to the subject will at once recognize as correct, that the short membrane, wherever situated, will indicate the edge of the placenta which had been the inferior, and that no further room is necessary for the passage of the mass in the way stated, than that which, folded upon itself, as we see it protruding through the external parts, it requires for its transmission ; and I consider that I was perfectly correct in asserting that in the multitude of cases in which the fœtal surface comes foremost, if the

long membrane be at the perineal margin, the placenta must have been on the anterior wall; if at the pubic resting on the posterior. This is the common-sense view of the question; and I have satisfied myself of its correctness by repeated observation. Moreover, I think the onus rests on him who denies it, to prove that the placenta can so turn itself round in the uterus as will enable the inferior edge to assume a superior position, which alone would vitiate the evidence thus afforded. It would have been easy to illustrate my description by a diagram, but I fear its introduction would not be compatible with your arrangements.

Having thus obtained a means of recognizing the former situation of the placenta, I determined to institute a series of observations, firstly, to ascertain how far the evidence to be derived from the membranes would tally with the stethoscopic examination; and secondly, how far the deductions to be drawn from both, and from the introduction of the hand in such cases as required it, would support Mr. Carmichael in assigning, as the seat of the placenta in ninety-eight cases out of a hundred, the lowest part of the back of the womb; that is to say, " within two inches of the lowest part of the cyst." The table published in the Dublin Journal was the result. It shows, that in every case the situation, as indicated by the stethoscope, and which every authority on the subject declares is that which the introduction of the hand will point out to be its real situation (as indeed I always found it), was confirmed by the inspection of the afterbirth, in the way I have mentioned. With respect to the stethoscopic examination, I may be permitted to observe, as my accuracy has been called in question, that having now for nearly three years devoted much of my time and attention to the cultivation of the instrument, in the magnificent field afforded by the Dublin Lying-in Hospital, it can scarcely be supposed I would commit any great blunder in its use. By the foregoing means I found that out of 100 cases, in 25 the placenta was attached to the anterior wall: in 10, to the left side, extending to the anterior wall; in 8, to the right side, also extending to the anterior wall; in 54 it occupied the posterior segment of the uterus, either in a central position,

or approximating, as it usually did, to one or other sides; and that of these posterior placentas, only 27 came " within two inches of the lowest part of the cyst." I am proud to perceive that a favourable judgment has been expressed of my researches in this particular by the Editor of the British and Foreign Review, of whose midwifery articles the profession entertains so high an opinion.

An attempt has been made to array against me the observations on this subject of Mr. H. F. Naegelé, because in 600 cases he discovered the placenta to have occupied the anterior wall in 13 only; but I consider of the two mine is the correct proportion, for the following reasons:—In assigning this as not an unusual situation, I am supported by Velpeau, who, out of 34 cases which he examined after death, found three placed anteriorly, (which would thus give in 600 cases a proportion, not of 13 only, but of 53; and by the standard authorities in midwifery, all of whom attest that the placenta may attach itself to any part of the uterus. Denman even states that it *most frequently* adheres to the anterior part. M. Naegelé, too, it must be remarked, drew his opinion of the situation of the placenta (except in two instances where he had a post-mortem examination) from the stethoscope alone; for, although he mentions in a note, that the membranes can give some evidence on this point, he does not appear to have availed himself of them. Now, that author sets down, as undeniable by the stethoscope, the large number of 180 out of 600 cases; and on turning to the passage where he explains why these cases were indeterminable, there is the following remark :—

" Although the point of insertion of the placenta may be generally ascertained with tolerable accuracy by means of the stethoscope, yet there are two classes of cases in which it affords no information on the subject. To the one belong those rare cases where no uterine sound is distinguishable; to the other, those much more frequent instances, in which the sound extends with equal intensity from both inguinal regions over the whole uterus."— *West's Translation*, p. 78.

In these cases, however, inspection of the secundines has enabled me to state, that in the former class the pla-

centa is small, and occupies about the centre of the posterior wall, and in the other it is attached to the anterior; and on this point I am borne out by a high authority, whom M. Naegelé does not appear even to have heard of, at least no allusion to him. "As to the fact of its being heard over the whole uterus," says Kennedy, in combating the views Dr. Häus had advanced, and which, strange to say, Dr. Hope still adheres to, namely, that the souffle is not in the uterine arteries, but in the aorta and iliacs : "as to the fact of its being heard over the whole uterus, if this gentleman had sufficiently inquired into the matter, he would have found that it is rarely, if ever, perceptible over the whole of that organ, although it is often met with over a greater or less extent of its anterior wall; and in such cases he might have detected the placenta attached there; also, where the sound could not be detected, he might have found it attached posteriorly."—*Observations on Obstetric Auscultation*, p. 72.

With such evidence in my favour, I think I may fairly say that a large proportion of M. Naegelé's undeterminable cases should have been added to the anterior, and thus my table and his would have corresponded very nearly in that particular. But I care not, for the purpose of rejecting Mr. Carmichael's arguments, what proportion the anterior position bears to the others; let him only grant me one case, as he has done in appealing to M. Naegelé, and I say his theory is untenable; for, in the first place, it is impossible, with his mode of expansion, that the placenta could ever adhere to that particular part; it must in every instance be turned over to the back of the uterus; and, secondly, according to him, such a case, if it could occur, should be attended with hæmorrhage, as must also those in which the mass adhered to the fundus. "Were the placenta here attached," he remarks in your periodical, "it is evident that the growth of the two organs would not correspond; that of the womb would exceed that of the placenta, and disturbance of the function of the latter would be inevitable, with its consequences on the mother and child." He expresses his intention, too, of making some remarks in a future number on abortion resulting from this cause. No doubt a very learned article

may be written on this subject; but, before it can carry any weight, he must first prove, beyond question, that such is the mode of growth and contraction of the uterus, which assuredly has not yet been done. He must, too, have altered his ideas very much with respect to hæmorrhage; for when I first made use of the argument, that according to his theory hæmorrhage should result in every case in which the placenta adhered to the anterior wall, he was quite offended that I should imagine he could suppose such a thing to occur as hæmorrhage, whilst the child remained in utero.

"And as for looking for hæmorrhage from detachment, partial or otherwise, while the child is in the womb," he remarks, "this I can only say, I never even hinted at it, nor can I see how it could possibly occur; and is it not a sad hardship on my part," he asks, "to have such silliness attributed to me?"—*Dub. Journ.* for Nov. 1839, page 223. One would be almost inclined to think, from this passage, he denied the possibility of the occurrence of accidental hæmorrhage; as an exemplification, however, of placental detachment by uterine action, I shall quote the following interesting case reported in M. Gendrin's Philosophical Treatise on Medicine —

"A woman, thirty-six years of age, the mother of many children, and in her eighth month of pregnancy, had a violent cough and fever. Being seized with labour, she sent for a midwife, who, after twelve hours of travail, saw her patient fall into the most alarming state. M. Delaforterie was sent for, but arrived only after her death. He instantly performed the Cæsarean section with every requisite precaution; and, on opening the fundus uteri, witnessed the escape of a gush of blood, which he estimated at three 'chopines' at least. This fluid left a large pouch between the placenta and the uterus, into which M. Delaforterie, on introducing his hand, was satisfied that the placenta had preserved its natural marginal adhesions with the womb."—*British and Foreign Rev.* for July last, p. 86.

Here now was a case which Mr. Carmichael, did he admit the possibility of such a kind of hæmorrhage, might fairly have adduced as a specimen of the bad results which follow the adhe-

sion of the placenta to the fundus; but unfortunately Naegelé has given seven, and I have given three cases, where the placenta occupied a fundal position, and yet no such consequence ensued. But in truth, in referring to M. Naegelé's table, Mr. Carmichael has been most unfortunate as regards his own theory and statement. If a slight discrepancy existed between the German author and me, a still greater difference can be pointed out between Mr. Carmichael and the umpire he has chosen. The former with confidence asserts, that at the termination of gestation, in 98 out of 100 cases, the placenta is situated low down on the posterior wall; according to the latter, it adhered in 379 instances out of 600 to the sides of the womb. It is not for me to say which opinion is likely to be correct; but, assuming that the lateral is the usual position, in what a predicament must M. Naegelé's placentas have found themselves. Attached to the sides of the uterus, and thus extending into both its posterior and anterior segments, one-half must have been securely lodged in a never-changing residence, whilst the other half underwent all the dangers of the ever-shifting scene—throughout pregnancy running the risk of being outgrown, and during labour subjected to the imminent hazard of being detached by uterine action. How strange that, amidst such dangers, the population of Ireland should not have been materially thinned!

But I insist that, according to the mode of growth described, the placenta should in every case be found, not anteriorly, nor even laterally, but occupying the posterior wall alone. If it be first attached to the fundus, and if its position be altered by the increase of the anterior wall, it should be in every instance (to use the author's own words) "turned over to the back of the womb;" and every single case in which it is otherwise situated militates against the doctrine advanced, particularly those in which it assumes and maintains throughout gestation an anterior position. As Mr. Carmichael never witnessed a case of this sort uncombined with some unnatural circumstance, I shall mention one, besides those I have already referred to in my papers, which it is in his power to examine for himself. A few weeks since

I removed the uterus from the body of a young woman, who died after a few hours' illness, in about the seventh month of pregnancy. The preparation I this day examined with Dr. Wm. O'B. Adams, the Professor of Midwifery to the Apothecaries' Hall, in whose museum it now is. We found the placenta still adhering to the centre of the anterior wall, to which the bladder (a sufficiently distinctive mark) is still appended. Why, I would ask, was not this placenta carried up, if this extraordinary and novel extension of the wall, on which it was implanted, was going on? Before this period one would imagine it should have advanced at least as far in its revolution —which, by the way, the author on another occasion humorously likened to that of a planet in its orbit—as far, I say, at least as the fundus, as it had only two or three months more to make its way downwards to its allotted position. But perhaps this will be considered a solitary instance, one in which the law of growth was reversed in its favour. Be it so; but I should like to know how it comes to pass that, in a very great majority of cases of partial placenta presentation, the placenta undeniably remains, up to the period of labour, attached to the very lowest part of the anterior wall? To my plain mind these indisputable facts are quite at variance with the theory proposed; but I have no doubt Mr. Carmichael can find some ingenious mode of reconciling them, for some men there are who will never own their mistake, and

" Though vanquished often will argue still."

But as with even such a doughty combatant the contest cannot last for ever, I shall say, in order to conclude on my part this long-continued discussion, which has now been extended into three periodicals, that feeling satisfied the mass of evidence I have brought forward, and the arguments I have used, are sufficient to convince any person who takes an interest in the matter, I shall not again enter into the question, unless some new fact of sufficient importance is adduced in support of this theory, which undoubtedly is as yet unproved, and, in my opinion, unprovable.—I am, sir,

<div align="right">Your obedient servant,
RICHARD DOHERTY, M.D.</div>

REPORTS OF CASES,

By H. M. Hughes, M.D.

Assistant Physician to Guy's Hospital, and
Physician to the Surrey Dispensary.

[*For the Medical Gazette.*]

Pleuritis.—There are a few rare affections both of the chest and abdomen, which, I believe, cannot either by their history, their general symptoms, or their local signs, be *always* distinguished with certainty from the effusions consequent upon inflammation of the pleura. Among such affections may be mentioned malignant disease of the lung, fungoid tumors, and other irregular growths of the liver, displacing the diaphragm, and encroaching upon the cavity of the thorax, which occasionally present all the constitutional as well as local characters of empyema. Ægophony, supposed by Laennec and his immediate followers to be almost pathognomonic of a certain amount of pleuritic effusion, has been stated by several recent writers upon diseases of the chest to occur very unfrequently in a perfect or characteristic form. In this opinion I entirely concur, as, after many years especial attention to thoracic disease, during which I have examined very numerous cases of pleuritis, I have very rarely had an opportunity of hearing well-marked ægophony; though modifications of the sound, as that accurately resembling the voice of Punch, and of a person speaking through a trumpet, or that which may be correctly denominated ægophonic bronchophony, are exceedingly common.

The symptoms of pleuritis, notwithstanding, are ordinarily sufficiently characteristic, and the accession, advance, and retrocession of the complaint, are generally most accurately marked by the signs afforded by percussion and auscultation. Some instances of the disease I have indeed myself witnessed, the nature of which could not, I feel assured, be accurately determined, without these important aids to diagnosis; unless a sharp pain in the side had been considered sufficiently indicative of an inflamed pleura. Pleuritis, it is true, is usually, though not universally, accompanied with pain, and the physician whose opinion as to the existence of this complaint was founded upon this symptom alone, though he would

be frequently mistaken in his diagnosis, would include the great majority of the cases submitted to his notice. But, independently of the few instances of latent pleurisy, of which he would take no cognizance, he would include diseases of an entirely different nature, and would probably treat, antiphlogistically, complaints, as rheumatic affections of the pectoral or intercostal muscles, and neuralgic pains, resulting from spinal or uterine irritation, which required for their relief or removal measures of an entirely different or even of an opposite kind. At the onset of some cases of pleuritis, pain is the only general symptom present, and it is by the physical signs alone that the physician is enabled to decide upon the inflammatory character of the complaint ; upon them alone must his treatment at that important period be founded, and upon a correct appreciation of these alone, therefore, is often dependent the speedily successful termination of the disease.

It is not my intention to enter upon the symptoms and diagnosis of pleurisy, accounts of which may be found in all recent systematic works. I shall therefore merely state, that the five cases of simple pleuritis mentioned in the table were accompanied with the ordinary symptoms, that they all terminated successfully under the ordinary treatment by bleeding, cupping, blisters, and calomel and opium, and that they presented no features of especial interest which render them worthy any particular notice. A case, however, which I have lately seen, so entirely confirms the truth of the observations I have made in reference to the importance of the signs afforded by auscultation and percussion, that I may be excused for detailing it in this place.

S. S., aged about 36, a pale thin woman, much marked with the small-pox, and of light complexion, came under my care as a patient of the Surrey Dispensary, May 19, 1840. She was of temperate habits, the mother of six children, and principally engaged in domestic household work. Ten days before I saw her, while in good health, she was affected with catarrh, and six days after was attacked with pain of the side. When visited, she was lying on her back, inclined towards the affected side, from which position she was with difficulty persuaded to move

for the purpose of examination. The pain was represented to be so very acute, and such exquisite tenderness existed upon slight pressure, or upon any movement of the trunk in a particular direction, as to lead to the supposition that it was of neuralgic or rheumatic origin. Her general appearance and symptoms tended rather to confirm the probability of the former. Her face was pallid; her lips deficient in colour; her tongue clean, pale, and moist; her skin soft and perspiring; her pulse small, frequent, and feeble; and her bowels confined. The resonance of the chest on percussion was generally natural, but very obvious dulness existed at the seat of pain in the left lateral region, and below the left scapula; the respiratory murmur, puerile at other parts, was in those specified entirely absent, and its place supplied by tubular respiration; and the voice, of the ordinary character and intensity over all the right, and the greater portion of the left side, was in the regions affected loud, shrill, and vibrating (imperfect ægophony). She was ordered—

> V.S. ad prima signa deliquii. Pulv. Rhei. c. Hydr. Chlorid. gr. xv.; st. sumend. Hydrarg. Chlorid. gr. j.; Ant. Potassio. Tartrat. gr. ¼; Opii, gr. ss. 4tis horis.

On the next day, as I was engaged, she was seen by the apothecary of the institution, who ordered a repetition of the venesection, and the other medicines to be continued.

21st.—The general symptoms now presented quite a different character, though the local signs were unchanged, and the pain, though decreased, was still severe. She complained much of thirst; the tongue was dry and coated; the skin hot and dry; the pulse firm and bounding; and the bowels again confined after the free action of the powder.

> Rep. Pulv. Aperient; Cont. Pil. Capt. haustus effervescent. 6tis horis, et applicetr. Empl. Cantharid. lateri dolent.

22nd.—The medicine had produced constant relaxation of the bowels, and she had passed several green motions; the skin was cool and moist; the tongue coated with a yellowish-white and moist fur; the pulse 96, small and compressible; the dulness on percussion and loud shrillness of the voice had

decreased, and a little crepitation was heard, apparently proceeding from a thin and superficial layer of the lung, immediately below the affected pleura.

> Intermitt. Mist. Rep. Pil. Capt. Mist. Cretæ. ʒiss.; post sing. sedes liquid.

23d.—Diarrhœa had ceased; she had but little pain; the physical signs of the complaint were less marked; but dulness still existed below the left scapula, and there were some indications of approaching salivation.

> Rep. Pil. noctemaneque. Applicat. Empl. Cantharid. scapulæ sinistr. ℞. Liq. Am. Acet. ʒss.; Mist. Camph. ʒj.; Vin. Antim. ʒss. M. ft. haust 6tis horis sumend.

25th.—Salivation profuse; had no pain; skin soft and perspiring; pulse 104, soft and compressible; respiratory murmur returning in the affected part; dulness on percussion much less, and resonance of the voice scarcely appreciable; for the first time complained of trifling cough, and of weakness.

> Rep. Pil. sine Hydrarg. Chlorid. om. nocte. Inf. Calumb. ʒiss.; Vin. Ipecac. ℥ xv. 6tis horis sumend. Gargarism sodæ chlorinatæ.

28th.—Complained of some aching pain; "weariness" in the affected side; but percussion elicited a good sound, and the voice and the respiration were natural.

After this date another blister was applied to the side; but she required no farther treatment than the exhibition of some tonic medicines to restore her strength. As, however, she was naturally feeble, and her weakness had of course been greatly increased by her disease and the means adopted for its cure, a considerable time was required for this purpose; she was, therefore, not discharged perfectly cured till towards the end of the following month.

Rheumatism.—Of the nineteen cases of this disease embraced in these reports, from being attended at the houses of the respective patients, I shall say very little, as they presented few features of particular interest; and as it is not my purpose here to enter *generally* into the history of any of the complaints that have been or will be noticed. Eleven of these cases occurred in females, of which eight were examples of the acute, and three of the chronic form of the complaint; and

eight in males, of which three were acute and five chronic.

The cases of acute disease all occurred in young persons, varying in age from 11 to 26 years, and were for the most part treated in the same way. In none of them was bleeding thought to be necessary. Some old and experienced practitioners almost universally commence their treatment of acute rheumatism by the abstraction of blood; others altogether abstain from the use of the lancet in this complaint, from an opinion, real or imaginary, that general bleeding has a tendency to render the complaint erratic, and thus to favour the production of pericarditis. On this question I am unable from observation to form a decided opinion. I may, however, state that in the hospital practice of a physician, who was in the habit of constantly prescribing venesection in the treatment of rheumatitis, I did not observe a greater proportion of cases followed by inflammation of the pericardium than in that of other physicians who did not prescribe this remedy. It must at the same time be considered at least a curious coincidence, that, after the opinion to which I have referred had been for some time current in England, Bouillaud commenced his much vaunted " saignées coup sur coup," and just at the same time " *discovered*" that rheumatism was frequently accompanied with pericarditis. I have never yet prescribed venesection for rheumatism of the joints, not because I feared the induction of pericarditis, but because I have not found it necessary for the removal of the complaint. The treatment I have hitherto adopted with success has been very simple ; and has consisted merely of the exhibition of a pill containing antimony and opium at night, or, if the pain has been very severe, twice or three times a day, with the occasional addition of one or two grains of calomel, if the constitutional excitement has been great, and if there existed any tendency to inflammation of the pericardium, or of other important organs. With these means has been combined a draught containing vin. colchic. ʒss. et magnes sulph. ʒj. to be taken three or four times in the 24 hours. In two or three days this medicine has produced copious yellow evacuations ; and at the same time I have almost always found the acute symptoms and the general excitement to cease, not, I believe, from the simple purgative effects of the medicine, but from the specific constitutional operation of the colchicum, of which the peculiar yellow evacuations are *one* of the principal indications. Immediately these effects of the medicine have been obtained, I have ordered the decoction of cinchona with 10 or 12 grains of the sesquicarbonate of soda, with the most beneficial results ; and the complaint has usually entirely disappeared in the course of a very few days. In two only of these cases was there any inflammation of the pericardium, and in both of them had a similar affection of that membrane existed before. In one of them, a married woman, of light complexion, and sandy hair, calomel was freely administered after cupping. Profuse salivation, in consequence, I believe, of renal disease, was induced in less than two days: the inflammatory affection of the chest immediately disappeared, and the soreness of the mouth, and other complaints unconnected with the recent attack, were the sole subjects of her subsequent treatment. The other case was that of a young woman, aged twenty-four, who, while under my care for disease of the heart, the consequence of a previous rheumatic affection, was after exposure to cold attacked with rheumatitis. She was on the second day removed to a hospital, in which, after she had recovered in a degree from the acute disease of the heart and limbs, and had suffered for several weeks from some obscure head symptoms, she died, as was proved by a cadaveric inspection, from a large effusion of blood upon the brain.

In the chronic form of rheumatism I have tried a great variety of remedies, but have hitherto found none which were uniformly successful. Certain boasted specifics have occasionally had a good effect, but in the great majority of instances their exhibition has been attended with little benefit. Some cases have yielded to remedies which appeared to have little or no effect in others of the same kind. In two instances only, after having tried a great number of other medicines and combinations without benefit, have I prescribed the extract of aconite. In both these cases it certainly appeared to have a good effect in relieving the

pain, but in one of the two its exhibition was followed by a papular eruption of the face and neck, which disappeared after its temporary suspension, and reappeared upon its readministration.

ON THE

LAWS WHICH GOVERN THE RISE,
DEVELOPMENT, AND DECLINE
OF EPIDEMIC MALADIES.

To the Editor of the Medical Gazette.

Sir,

My last communication will have put your readers in possession of some of the principal facts recorded in the Second Annual Report of the Registrar-General, regarding the late variolous epidemic. Mr. Farr, to whose valuable labours we are all so much indebted, is not content with a simple statement of his statistical researches, but he enters the thorny paths of œtiology, and throws out some hints regarding the origin, progress, culmination, and decline of epidemic maladies. These suggestions, founded on that extensive collection of facts to which Mr. Farr's official situation gives him access, appear to be well deserving of notice in your journal; and I now proceed to consider them, adding some comments of my own.

Many of the causes of death, he begins by remarking, act with equal force from year to year. Some are regulated by the seasons, and increase or decrease with changes in the atmospheric tem

perature. A third class of diseases are the epidemics which follow laws of their own. They remain stationary for months, years —nay even, as the records of medicine teach us, for centuries;—then suddenly rise, like a mist from the earth, to shed desolation on nations, and again to disappear as rapidly and as insensibly as they came. The origin of such diseases is necessarily obscure, but that obscurity has proved no stumbling-block in the way of medical theorists; some of whom have attributed them to mysterious changes in the atmosphere, some to terrestrial emanations, some to the agency of animalcules, some to heat, some to the deterioration of food, while not a few have thought that in the existence of a contagious principle the whole difficulty was solved.

Mr. Farr begins by shewing that the temperature of the atmosphere and the revolution of the seasons had nothing to do with the great variolous epidemic of 1837-38. A table with which he furnishes us (page 92) demonstrates that at the very period when the epidemic was at its height in one place, it was declining in another, and just commencing in a third. Thus, for instance, in the autumn of 1838, small-pox culminated at Manchester, (proving fatal in three months to 180 persons) while it had entirely ceased at Bath, was just beginning in Norwich, and was gradually declining in London. The epidemic culminated, or reached its maximum degree of intensity, in the several towns of England and Wales in the following order:—

Table exhibiting the period of culmination of the variolous epidemic in twenty-eight of the principal towns of England and Wales.

Period.	Date.	Towns.
1	July to Sept. 1837	Liverpool, Bath, Leicester.
2	Oct. to Dec.	Exeter, Wolverhampton, Bristol.
3	Jan. to March 1838	Taunton, Clifton, Worcester, Merthyr-Tydfil.
4	April to June	London, Birmingham.
5	July to Sept.	Haverfordwest, Pembroke, Bridgewater.
6	Oct. to Dec.	Leeds, Manchester, Plymouth.
7	Jan. to March 1839	Sunderland, Newcastle, York.
8	April to June	Norwich, Preston, Stockport.
9	July to Sept.	Oxford.
10	Oct. to Dec.	Salford, Bradford, Macclesfield.

Interesting as this statistical document is, we shall hardly, I apprehend, be justified in trusting to it, so far as to exclude atmospheric changes altogether from the possible causes of epidemic prevalence. After a lull of eighteen or twenty

months, small-pox is again become epidemic in London. The first approaches of this new assault were perceptible in the first week of October. At the present time the weekly deaths average nearly sixty. It is, I think,

highly probable that this diffusibility of the variolous contagion is connected with that remarkable dampness of the atmosphere, which has led to such heavy floods both in this country and throughout the south of France. In former times the dependence of epidemic small-pox upon a humid state of air was universally admitted, and the events of the present month afford a singularly strong corroboration of the doctrine.

The hypothesis that the immediate cause of epidemic disorders may be found in the generation of minute insects, is considered by Mr. Farr as worthy of some comment. He gives an abstract of the opinions entertained by Dr. Henle, of Berlin, upon this most abstruse question. According to this author, each epidemic disease has its specific animal contagion, its specific genera of infusoria. Dr. Henle, it is remarked, has, by a variety of curious analogies, given great probability to the theory of animalcular origin, but one little circumstance has been omitted—a trifle probably in the eyes of the German professor. Dr. Henle has never seen these epidemic infusoria, which is the more surprising when we reflect that Henle is one of the best microscopic observers of Germany.

Mr. Farr, rejecting this and all other hypothetical explanations of the origin of epidemics, arrives at the following conclusion:—" They are generated at intervals, *in unhealthy places*, spread, go through a regular course, and then decline; but of the cause of these evolutions no more is known than of the cause of the periodical paroxysms of an ague. The body, in its diseases, as well as its functions, observes a principle of periodicity. Its elements pass through prescribed cycles of changes, and the diseases of nations are subject to similar variations."

But though Mr. Farr thus luminously descants on the origin of epidemics, he subsequently admits that there is reason to believe that the practice of inoculation led to the extension of the epidemic small-pox of 1838, by artificially diffusing the infection. I cannot help thinking that too much stress has always been laid on inoculation as instrumental in the diffusion of small-pox. It certainly had nothing whatever to do with the growth and development of small-pox in London during 1838, where the disease raged much more severely than in any part of the country where inoculation was practised. This question is especially deserving of attention at this time, because the late Act for the extension of vaccination has effectually abolished inoculation; but it remains to be seen, whether it will abolish, or in any notable degree affect the amount and severity of variolous epidemics. It was remarked, more than sixty years ago, by very competent observers, that the artificial diffusion of small-pox by inoculation was very limited, and that the influence of such an agent was prodigiously over-rated. When no epidemic disposition existed, inoculation, it was observed, seldom did harm, and when such a disposition *did* exist, the disorder spread equally, whether inoculation was practised or not. I have a strong impression that many years will not pass over our heads before the truth of this doctrine in pathology will be made abundantly manifest, even to those who are now loudest in declaiming against the dangers of inoculation.

Mr. Farr has attempted, with his usual ingenuity, to trace the laws which regulate the rate of *epidemic decline*. He remarks, that the decline of the variolous epidemic was less rapid than its rise. The advance of small-pox is first at an accelerated, then at a retarded rate. Having attained its climax, it declines, first, at a slightly accelerated, then at a rapidly accelerated, and lastly, at a retarded rate, until the disease attains its point of minimum intensity, when it remains stationary.

Another point to which Mr. Farr draws attention is, the important question, whether the simple principle of contagion is sufficient to explain the rise and propagation of this epidemic? That the small-pox is contagious, is admitted on all hands; but it will be found that something more than contagion is required to explain the phenomenon of *epidemic expansion*. The disease, as he truly remarks, is always and equally contagious, and a certain number of deaths are caused by it in all seasons, and in every county in England. The facilities of intercourse, and the frequency of contact with the sick, are not greater when the disease is increasing than when it is declining.

They remain the same, whether the disorder be at its climax of severity, or its point of minimum intensity. Five persons die weekly of small-pox in London, when the disease is not epidemic. In the spring of 1838, these five deaths, having progressively advanced through the successive steps of 10, 15, 20, 31, and 58, multiplied at length to 88, and then steadily declined in a like series of measured steps, until they reached the original minimum of 5. The variolous epidemic of Manchester commenced in October 1837, when that of Liverpool was declining; but, as Mr. Farr well observes, it would be very false philosophy to assert that the commercial intercourse between these towns had any thing to do with the rise of the epidemic at Manchester. The Registrar's return shews that isolated cases of small-pox occurred in Manchester during the preceding months, and the same causes which occasioned epidemic prevalence in Liverpool would have led to the same results in Manchester, in spite of all quarantine regulations.

The simple principle of contagion, then, though it undoubtedly contributes to the diffusion of epidemic malady, is wholly insufficient to account for its sudden rise and subsequent development. As little is it capable of explaining the singular circumstances attendant on the decline of an epidemic visitation. It has, indeed, been contended by some, that an epidemic disorder lessens, and ultimately ceases, because the subjects of disease are exhausted, just as a fire goes out for want of fuel. But this explanation is little trustworthy, for it happens not unfrequently that an epidemic returns after a brief interval of repose, and, by its subsequent ravages, effectually demonstrates the futility of this notion. We are seeing this exemplified in London at the present moment : many are now attacked, who escaped the perils of 1838.

The conclusion to which all this tends is, that the phenomena of epidemic culmination and decline are as little understood as those of epidemic origin. Careful and reiterated observations, on a large scale, may, however, some day afford us a clue towards the elucidation of these interesting questions ; and, if Mr. Farr's observations and statistical documents have

done nothing else, they have at least cleared the way for future observers.

They have removed some of those delusions which have hitherto obscured our views of epidemic malady, and have made us see how little we really now know, and how much remains for future inquirers to determine.

I am, sir,
Your obedient servant,
GEORGE GREGORY.

31, Weymouth Street, Nov. 21, 1840.

CASES OF COMPOUND FRACTURE OF THE CRANIUM WITH DE-PRESSION,

WITH SOME REMARKS ON THE TREATMENT OF SIMILAR CASES.

By JOHN CHARLES HALL, M.D. F.L.S.

Fellow of the Royal Medical Botanical Society, and Member of the Royal College of Surgeons, &c. &c. &c.

(For the London Medical Gazette.)

CASE I. — During the present year George Spencer, assistant groom in the stable of Earl Spencer, in removing some dung from one of the horses was kicked upon the head. I saw the poor fellow shortly after the injury had been sustained. There was a small wound upon the side of the head about the size of a shilling, from which there was a considerable flow of blood. It was evident the wound had been made by the heel of the shoe, which, upon examination, was found to be raised (what the blacksmith terms "turned up"). This portion of iron had been driven through the scalp with sufficient force to fracture the frontal and parietal bones on the right side of the head, and on introducing the finger the depressed portion of bone could be very easily detected. The man was a little stupid, and complained of being sick ; the pulse was weak ; the hands and feet cold. The wound was very carefully brought together with adhesive plaster, and supported by a bandage ; the hair was removed from the head, and the man sent to his bed. Two hours after the accident I saw him again : pain in the head ; skin hot and dry ; pupils slightly dilated ; has been very sick ; pulse 100.

V. S. ℥xiv. Cold water to the head.
Two grains of Calomel every six hours.

7th.—Slight pain in the head; skin hot and dry. Saline aperients; cold water to the head. The bowels have been freely opened.

Vespere.—Still complains of pain; pulse 120.

R Pulv. Scam. gr. iv.; Hydrarg. Chloridi, gr. iii. hac nocte.

To continue to take nothing but a little tea and toast-water, which has been his only food since his accident. Ice to the head.

8th. — Pupils more dilated; more pain in the head; intolerance of light; pulse 120, hard and full.

V.S. ℥xvj. Saline aperients, with antimony.

Evening.—Blood drawn away a good deal "buffed;" says he is much relieved by bleeding; bowels freely opened. Continue the saline mixture with emetic tartar. Two grains of calomel at bed time.

9th.—Less pain in the head; wound looks healthy; slight puffiness of the scalp, into which a lancet was plunged; pupils still dilated. To have a little mutton broth.

10th.—Pain in the right ear; puffiness of the integuments entirely removed; mouth slightly affected by the calomel; pulse 100, full, and rather hard.

V. S. ℥viij. Omit the mercury.

11th. — Much better; blood taken yesterday buffed; pulse 90; skin moist.

R Liq. Ammon. Acet. ℥ii.; Spir. Æth. Nit. ℥ss.; Aq. Menth. Vir. ℥x. sextâ quaque horâ. Pulv. Jacobi, gr. iv.; Hydrarg. c. Creta. gr. vi. hac nocte. Cold water to the head.

12th.—Still improving; has now little pain in the part, and appears anxious to leave his bed. He was, however, still confined to his room, his bowels kept well open, and his diet mutton broth and tea. He gradually recovered under this treatment, and is now as well as before the accident.

Case II.—For the particulars of this case I am indebted to my old friend Mr. Lane, the Lecturer on Anatomy. A little boy of the name of Lee, between four and five years of age, was playing in a stable yard, when the shafts of a phaëton fell upon his head, and the iron projection on the under surface of the shaft for the purpose of fixing the harness made an indentation into the child's head, into which you might place the end of your finger. The scalp

was divided, and the bone depressed to the depth of a quarter of an inch. The little fellow was stunned for a short period only, vomited, soon recovered its circulation, and in a few hours appeared in its ordinary state of health. Nothing worthy of mention was done for the child: symptoms were watched for, but none appeared; a piece of bone larger than a sixpence exfoliated, and after the wound healed a considerable depression remained.

Case III.—A man employed in building some houses was standing under a ladder, when a piece of iron, the end of which was about the size of a shilling, fell upon his head, passing through the integuments, and beating in a portion of the skull. The man said, "That nothing was the matter with him, that he felt stunned for the moment, but was then quite well, and that if his wound was *done up* he could go to work again." This opinion was over-ruled, and it was decided that the trephine should be used, for the purpose of raising the depressed portion of bone. The man said nothing, not knowing what a trephine was, but when it was brought, declared "he would take very good care that no one should make a hole into his head." The wound was carefully closed, the man sent to his bed, and largely bled: symptoms were looked for, but none arose, and in a short time he was quite well.

Case IV.—Mr. P——, at the age of 16, whilst riding down a very steep hill was thrown off his horse, and fell with very great violence on his head. When taken up he was quite insensible, and a severe wound of the head was found to have been received. The surgeons called in, on examining the injury found that the scalp had been divided over the right parietal eminence, and the bone below fractured with considerable depression. According to the admitted principles of surgery in those days the scalp was divided on either side of the wound, and the fracture traced out to its ultimate terminations with scrupulous and laboured care. What was to be done? Compound fracture of the skull, with depression and symptoms of pressure upon the brain. The trephine must be used, and preparations were accordingly made for performing the operation; which, however, was suddenly put a stop to by the gentleman

recovering his senses, and by the re- moval of all symptoms of concussion and compression. The question now arose whether it was safe to allow the case to go on without elevating the depressed portion of bone ; this part of the business was, however, decided by the patient, who declared that no opera- tion should be performed : he was, therefore, removed home, and the wound allowed to heal, and notwithstanding the additional scalping of the surgeon, it did so without any untoward symp- tom. Forty years have now rolled away since the accident : the gentleman is still alive, with a depression of the right parietal bone, of about a quarter of an inch deep, and an inch and a half long : he has never suffered any pain or in- convenience from it : he is the father of a numerous healthy family, one of them in good practice as a surgeon, and to him I have to return my thanks for the outline of this truly interesting case.

CASE V.—A man was brought into the hospital in Paris, under the care of M. Roux. He had received a blow upon the head, wounding the scalp and fracturing the frontal bone, which was considerably depressed. He was quite insensible for some time, but recovered sufficiently to walk to the hospital : he complained of pain in the head, which he wished to have dressed, in order that he might return to his employment. He was, however, advised to remain in the Hôtel Dieu, which he did for three weeks. He was only bled once, and kept upon a very low diet. The man never had a bad symptom, and per- fectly recoverd.

CASE VI.—A little boy was admitted into the Hospital of University College, London, under the care of Mr. S. Cooper, for an injury of the head re- ceived five weeks before. There was a fracture with considerable depression, with a wound leading down to it. The seat of injury was the frontal bone, the accident being occasioned by a blow from the handle of a pump. As the lad was sensible he was only bled and purged, a cold lotion applied to the head, and an antiphlogistic diet strictly enjoined. No serious indisposition came on, and the lad soon got well, although a considerable depression re- mained; and, adds Mr. Cooper, " I have seen many cases of depressed bone with a wound of the scalp do well without the use of the trephine." Let us now direct our attention *to the treatment of similar cases.*

We have selected the above from several cases which have come more particularly under our own immediate observation. We have perhaps in the course of our experience seen as many more do well in which nature was al- lowed to work her own cure. We have seen some get over the operation of tre- phining, have seen many die, and have from this circumstance been led care- fully to examine the subject for some years past, and to come to the conclu- sion hereafter mentioned. If the reader wishes for additional cases, he may refer to the writings of Dease, Desault, Abernethy, Crampton, and S. Cooper.

No operation has been more dis- cussed than the one more particularly under consideration ; the champions of the trephine and the anti-trephiners appearing rather anxious to gain advo- cates in favour of their particular opi- nions, than to discuss the subject with a due regard to the facts before them, and from facts alone to draw their con- clusions.

In all cases of injury of the head, it will be very important to inquire whether the patient has remained in- sensible from the first infliction of the injury. If he has done this we have in the first instance every reason to hope that the symptoms are the result of concussion. In the case of the little boy Lee, (Case II.) though stunned by the blow, the brain gradually recovered its proper functions. Mr. P——, (Case IV.) remained insensible for a con- siderable time, until the side of his head was half scalped by the surgeon, and yet he awoke in time to prevent the operation, and remains alive to the present day. The shock the brain has received by the concussion will continue to diminish, and after a time cease altogether, for if the force applied, when the blow is received, be not sufficient to produce alarming symptoms, it will not do so afterwards, for it is not rea- sonable to suppose that a cause insuffi- cient to produce them in the first in- stance will do so when its power is considerably diminished. If immedi- ately after the infliction of the injury the man gets up and walks away, it is clear that the brain has not suffered from concussion ; still the patient re- quires to be well watched, for in an

hour he may become drowsy, perhaps insensible, and then the case must be regarded as one of compression. This cannot, however, be of use on all occasions, for we may have concussion and compression combined. Still the rule is a good one, and ought never to be lost sight of.

In many cases of concussion of the brain, we have seen much injury produced by the abstraction of large quantities of blood. A man falls from the top of a house ; he is taken up insensible, with cold hands and feet, and a feeble pulse. The pulse rises a little, and some blood is immediately taken away. It rises again, becomes a little fuller, and some more blood is added to the first, and this is again and again repeated, and in time the pulse will become weaker, and the patient sinks and never recovers. We are aware that the opinion now expressed differs from that entertained by many surgeons, and yet repeated observations have induced us to conclude that concussion of the brain acts upon the general system in nearly the same manner as syncope arising from irritation, fever, grief, or any other cause, and in the treatment of which blood-letting is known to be injurious.

" Immediate dissolution, like syncope, probably depends upon an affection of the brain induced by great loss of blood, or the loss of even a very small quantity in a constitution enfeebled by disease." Now if this opinion of Dr. Marshall Hall be correct (of which there can be no doubt) it will appear very clear that the abstraction of even a very small quantity of blood, when the functions of the brain are as it were suspended, and its energies considerably weakened, is likely to be productive of the most serious consequences.

We are at a loss to account for the way in which a person five minutes before in the possession of health, and capable of supporting the evacuation of a large quantity of blood, becomes by a blow upon the head, which does not fracture the bone, unable to bear the loss of a wineglassful, yet, nevertheless, attentive observation has convinced us of the fact, and all who take the trouble to read this page of nature's work will come to the same conclusion. Be it, however, remembered that although we may have a very correct knowledge of the structure of the brain and of its

several parts, yet we must also confess that we have much to learn before we can state the manner in which its several functions are performed. We have seen the dissection of several brains in which the person was said to have died from concussion induced by a severe blow upon the head, without being able to discover any traces of inflammation, and yet the symptoms during life were such as pointed to the brain alone as the seat of injury. From the want of traces of inflammation after death in cases of concussion, as well as from the evident injury we have seen produced during life, we do think the frequent abstraction of large quantities of blood both uncalled for and injurious in cases of concussion of the brain. We remember the case of a man who was knocked down by the Dart coach, in the streets of Kensington. When called upon to attend him, we found his arm bound up, and a chemist about to open a vein. The man was cold ; his lips bloodless ; nor could either the pulse at the wrist or the beating of the heart be felt. Some brandy and water was given ; he could not swallow. He was placed in a warm bath, rubbed dry, and put into a warm bed ; the head shaved, and covered with cloths dipped in cold water. It was twenty-four hours before he spoke at all, and many days ere we could get him to do more than answer " yes" or " no," or " leave me alone." It was three days before it was thought necessary to take away any blood. Eight ounces abstracted relieved a fixed pain in the head, and the man perfectly recovered.

The question now more particularly before us is, ought the trephine to be used in cases of compound fracture of the cranium, in the absence of symptoms indicative of pressure upon the brain ?

It is, no doubt, a matter for serious thought, a subject on which no man would venture to give an opinion, without first devoting to it the most attentive consideration. If the bone could be raised without additional injury to the soft parts—if the portion of skull could be lifted from the brain without violence, without opening the cavity of the cranium, and exposing the brain and its membranes to additional injury—then we should have no doubt upon the matter ; but can we do so ? Experience answers, no. If, however,

after waiting a reasonable time, the symptoms of compression remain, the patient must not be left to die. We have numerous cases on record in which the operation has succeeded in snatching individuals from the jaws of death: perhaps the most interesting is that related by Mr. S. Cooper, of a man belonging to the 44th regiment, who was struck by a musket-ball on the right parietal bone, which had been exposed, but without any appearance of fracture. The poor fellow being all but dead, the trephine was applied; the external table came away, showing the internal table driven into the brain: this was removed; the man at once got up, dressed himself, and perfectly regained his health, without a single bad symptom. But in the absence of symptoms denoting pressure upon the brain, we are justified in leaving the case without the performance of this operation. The cases already quoted, the numerous ones on record, prove that the brain may bear a slight degree of pressure without injury. "But you do not trephine for symptoms that are present; you do so to prevent others which may possibly arise." If, however, the brain accommodates itself to the pressure in the first instance, we are at a loss to conceive why it will not continue to do so: if it performs its proper functions soon after the infliction of the injury, neither reason nor experience teaches that it will not do so throughout the patient's life, as in Case I., Case IV., and the cases related by Mr. Abernethy and others; and it is notorious that the experienced Desault, in the last years of his practice, abandoned the operation altogether, owing to the dreadful fatality which attended it in the Hôtel Dieu; and even now, both in France and England, the opinion of its most strenuous supporters begins to wave.

Mr. Liston, in his work on Operative Surgery, remarks that the upper part of the brain often bears from the first a great deal of pressure with impunity, or it becomes accustomed to it, or the symptoms abate, the patient recovering, with a great portion of the bone completely under its natural level. He, however, contends that the use of the trephine is necessary in punctured fractures: "the presence of the numerous sharp spiculæ from the internal table, for even a short period, is frequently

followed by intense inflammatory action, propagated to the brain and its more immediate investments. At all events, even if he escape this danger, he is apt to suffer at a later period from abscess under the bone, occasioned and kept up by the dead portions." This opinion, coming as it does from this experienced surgeon, demands our most serious examination. The case of Ridley; the boy Lee; that of the man struck with the iron bar; the case of the woman struck by a brass candlestick, and the boy kicked by a horse in Smithfield (the two latter related by Mr. Abernethy), would almost cause us to pause ere we resorted to the operation, even in punctured fracture. Is it too late to have recourse to it at a later period, when we have symptoms proving such injury to exist?

We think the case of the nephew of Lord Brougham, related by Mr. Crampton, bears upon this point, and proves that even fragments may be driven into the substance of the brain without their immediate abstraction being required or warranted, although we should endeavour to remove them as a general rule; nevertheless it will be sure to have exceptions. In the case just mentioned the moment Mr. Crampton touched a large portion of bone with the intention of removing it, (for the fragment was buried in the brain,) the body became convulsed, and the patient moaned deeply; all further efforts were desisted from—the case was left to nature—strict antiphlogistic measures resorted to, and at the end of twenty-two days the small pieces of bone were discharged by the process of nature. And what says the experience of an old army-surgeon—of Mr. S. Cooper? If the depressed portion of bone be denuded by a wound of the scalp, a trial to raise it with the elevator may sometimes be proper, even though urgent symptoms of pressure do not exist: in such cases Sir A. Cooper sanctions the use of the trephine; yet my own experience and reflections would induce me to abstain from the operation.

CASE VII.—Since the above portion of the paper was written, in looking over an old note-book, I find the case of a man attended by me about two years ago. In that colony of Irish, Kensington Buildings, a policeman informed me that a fight had taken place,

and on following him to the spot we found a poor fellow upon the ground senseless.   Upon cleansing his head from the mass of clotted hair and blood which was upon it, three very severe wounds were discovered.   The scalp was much injured, owing to the wretch who inflicted the injury having first beaten his victim with a stone, and then jumped upon him with his nailed boots.   One of the wounds extended from the temporal to the parietal bones, and on introducing the finger a fracture with very considerable depression presented itself.   While debating what should be done, the man began to turn in his bed, was sick, and shortly after spoke, asking " if they had got Black Ned," which it appeared was the name of the man who had injured him.   He was bled, the bowels well opened, and a poultice applied to the head, for it was vain to attempt to heal the wound by the first intention ; yet, notwithstanding the depression of the bone, the age of the patient (forty-six), the contusion of the integuments, and a constitution enfeebled by want and intemperance, the man recovered without a bad symptom.

It will then, we think, appear that we have before us a sufficient number of facts to warrant the conclusion that, in numerous cases in which the skull has been fractured, and the bone driven down upon the brain, no inconvenience has been experienced by the patient. That some degree of pressure can be sustained by the brain is clear in the first instance from the absence of pain or headache immediately after the injury ; that such inconvenience does not arise long afterwards is obvious by an examination of numerous cases ; that of Mr. P——, (Case IV.) is confirmatory of the fact, as are also the cases related by Mr. Abernethy and Mr. Hill.

We grant that severe indisposition frequently continues before the patient returns to a state of health—we grant that after severe fracture, with depression, the issue is often doubtful, and the scale is poised equidistant between life and death ; but while we admit this we must admit also that these symptoms are often present in cases in which the bone has been elevated, and in cases where you have no fracture, but simply a wound in the integuments. Had the trephine been used in the case of the groom of Earl Spencer the man

might have got well; no bad symptoms might have arisen had the same anti-phlogistic treatment been resorted to, and had the result been the same the advocate for the trephine would have quoted it as an instance of the necessity of elevating the bone in all cases, to prevent symptoms which were kept down by the lancet and purgatives, without running the risk of exposing the brain.

We therefore are justified in coming to the conclusion that the brain can bear considerable pressure without injury ; nor can we see what arguments can be brought to bear against the opinion of Abernethy, that the brain accommodates itself to the pressure, and that which can be sustained at first is not likely to be productive of injury at some future period. Even if in cases of internal fracture the internal table is starred—if fragments are driven upon the brain, we think we are not justified in performing the operation in the absence of symptoms denoting such a state of things to be present.   Mr. Birch relates the case of a negro, who received a blow upon his head, fracturing the skull.   Shortly afterwards he was seized with epileptic fits, which continued for many years. He was admitted into the hospital, and a portion of the bone found still depressed. It was removed with a trephine with considerable difficulty, owing to a little spica of bone which had entered the dura-mater, and penetrated the brain.   The man perfectly recovered.

If the operation were in itself unattended with danger, that would be an unanswerable argument for its employment in all cases of compound fracture with depression ; but this unfortunately is not the case.   Now, as it can be clearly proved that injury done to the integuments and bone, where there is neither fracture nor concussion, is often productive of fatal inflammation of the brain, the argument to employ the trephine for the purpose of preventing inflammation is untenable, for the additional injury inflicted in its application will tend rather to increase than to diminish it.

We come not then to this conviction without a due examination of the subject ; but with numerous facts before us we can come to no other conclusion —we can lay down no other rule than this, viz. That the trephine ought never

to be used, even in cases of compound fracture of the bones of the head with depression, without symptoms denoting pressure upon the brain.

It appears that no harm results from delaying the operation: it is proved that cases frequently do well without it; it is proved that if antiphlogistic measures are continued upon the subsidence of the inflammatory symptoms attendant upon or immediately following the injury, the pressure may be found of little consequence. Nothing is lost by delay. The risk of increasing the danger by operating upon parts in an active state of inflammation is avoided; at any rate you avoid the danger of increasing the inflammatory action set up in the parts by the injury inflicted, and the reasonable hope may safely be indulged, that in the great majority of cases the danger will not be incurred of making a hole into the cranium, through which the brain will be very liable to protrude.

Doctor Reese, of America, informs us "that in the United States the trephine is now much more seldom used than formerly:" in France and England it is daily growing into disuse: it is an operation not to be performed without the most urgent necessity— "gravis tamen satis est operatio, ut nunquam nisi indicationes adsint instituti debet."

In reading over what we have already written we find that we have omitted to caution the patient as to the mode of life to be led for months after the infliction of an injury of this nature. Excesses of any kind must be carefully avoided, the bowels kept constantly open by aperient medicines, and every thing shunned that can tend to produce the slightest excitement of the system.

Bath Place, Kensington, Oct. 1840.

NEW OPERATION FOR LATERAL CURVATURE OF THE SPINE.

To the Editor of the Medical Gazette.

Sir,

I feel much pleasure in transmitting to you the particulars of an operation which I performed on Wednesday last, in the presence of Mr Coulson, and Mr. White, Demonstrator of Anatomy at the Medical School, Aldersgate Street; and as it is one that has never before been

performed in England, it may not perhaps be deemed an unacceptable communication to your valuable journal.

The subject of operation was a lad, 17 years of age, who had been affected with lateral curvature of the spine three years. His business was that of a printer, in which occupation he was daily employed in pulling the press, whereby he was in the habit of putting into excessive action the latissimus dorsi and rhomboid muscles of the right side, whilst those on the opposite were comparatively inactive : the consequence of this was, that in six months after his apprenticeship to the business he began to feel an uneasiness, and, as he describes it, a burning sensation in the upper and right side of the back : this was shortly after followed by an enlargement of the right shoulder, and a lateral curvature in the dorsal region. This continued to increase, so that when he applied to me, about eight months since, the deformity was very striking. On examining the back, I found the deviation to extend from the last cervical to about the sixth dorsal vertebra : below this the vertebræ suffered no displacement, but occupied precisely the mesial line of the back,—a circumstance most unusual in a case of so long standing. The right shoulder was considerably elevated above its fellow, with a corresponding displacement of the clavicle, but there was no excurvation of the ribs : on either side they retained their natural situations.

The rhomboid and trapezius muscles were greatly enlarged, and by bringing the forearm across the chest were so stretched that a finger could easily be passed beneath the rhomboideus minor. The muscles on the left side were so diminished in bulk that they could scarcely be traced,—a circumstance I hold of great importance in the operation.

His general health had been good, with the exception of suffering occasionally from enlarged cervical glands. As his means would not allow him to adopt my regular course of treatment for these affections, I recommended him to keep as much as possible in the prone position, to use my extension apparatus, and to employ certain forms of exercise.

In consequence of the nature of his employment he was prevented from pursuing this course with the regularity

wished, and the right arm was daily occupied in pulling the printing press. I lost sight of him until last week, when he again applied to me, and not finding the slightest improvement in the state of his back, I explained to him the nature of an operation which had been performed by M. Guerin, in Paris, and lately by Dr. Hunter, of Glasgow, and recommended him to undergo it, as the only probable means of effecting a cure ; and without hesitation he assented.

The patient being placed in the prone position, with the chest considerably elevated, and the head hanging over the table, Mr. Coulson produced tension of the muscles on the concave side of the curve by drawing the left arm forwards, whilst Mr. White, by raising the right shoulder upwards and outwards, kept the rhomboid and trapezius on the stretch. I then introduced my knife (which was about four inches in length, and the eighth of an inch in breadth) as close to the ribs as possible, midway between the inferior angle of the scapula and the spinal column, and carried it upwards as far as its superior angle : I then withdrew the knife, bringing its cutting edge in contact with the anterior surface of the muscles, and as close as possible to the integuments, without wounding them, and in this way completed the operation, which occupied less than a minute. The loss of blood was trifling, and the patient complained of very little pain.

This case is interesting, inasmuch as it establishes the fact, that deformities of the spinal column are not always dependent on a diseased action of the muscles on the concave side of the curve, but that many of the occupations of life have a tendency to produce lateral curvature of the spine, by exciting unequal power over the antagonizing muscles, and on one side reversing the mode of action, as was seen in this case, the shoulder being made a fixed point towards which the spine was forcibly drawn.

In the curvatures that are met with amongst young children and delicate females, a totally different course is at work, and the muscles on the convex side of the curve are considerably diminished in size and density in consequence of their elongation ; being made to take a circular course around the projecting vertebræ, and, by the same rule, those on the opposite side having

become shortened, acquire an increase of action, and are firmer and stronger.

This case also strengthens the views I have adopted in the third section of my work on "Lateral Curvature," and which I think prove beyond a doubt the fallacy of Mr. Shaw's argument, in regarding the deformity of the dorsal vertebræ as a result only of a primary curve at the loins ; for in this instance not the slightest trace of deformity existed below the sixth dorsal vertebra.

I remain, sir,
Your obedient servant,
G. B. CHILDS.

Wood St., Cheapside, Nov. 20th, 1840.

FIT AGE FOR VACCINATION.

To the Editor of the Medical Gazette.

SIR,

On reading the regulations regarding Vaccination, issued by the Guardians of different parishes, as authorized by a recent act of parliament, they gave me the impression that very circumscribed views must have been taken by parliament when it passed that enactment. In the first place, it implies that small-pox can only be engendered from personal infection, and aims at its complete extermination. In the second place, the proposed means of accomplishing this desideratum is the vaccination of infants at the early age of six weeks.

Before this doctrine of extermination was made the basis of such regulations, the main point of the doctrine itself should have been established, viz. that small-pox,—unlike hooping-cough, measles, or chicken-pox, — has no other origin than that of being imparted from one individual to another. This point has not, however, been proved : on the contrary, the faculty could produce an abundance of evidence to prove that small-pox often springs up, in an isolated manner, in towns, villages, and in districts, under circumstances which afford no reason whatever to refer it to an infectious origin, but as if engendered, independently, in the individual's own frame ; and that it sometimes makes its appearance as an epidemic, in different parts of a town, at periods within a day or two of each other.

Although the public may be lulled

by an act of parliament into a false
notion of security, yet the faculty
would expect,—even if the disease could,
by early vaccination, be completely
extinguished for a time, which is
scarcely possible, — that it would, if
vaccination were then to be neglected,
soon spring up again as an epidemic.

With regard to the period of vacci-
nation. Vaccination on the sixth week
appears premature, and therefore calcu-
lated to defeat the object it is intended
to fulfil.   In making this remark I
shall probably differ from most of the
faculty; let it be, however, remem-
bered that a new-born infant is formed
of merely a temporary substance,
scarcely any part of which continues
to compose the body of the child when
six or eight months old.   Therefore, to
implant in this changeable body the
principal of the vaccine virus is not to
endow its future substance with the
power of resisting the infection of
small-pox.   1 am induced to submit
this proposition for the consideration of
the faculty, it having been my practice
not to vaccinate children at an earlier
age than eight months, unless small-
pox were occurring close in the neigh-
bourhood, and not having had, in con-
sequence 1 presume, a single case of
failure.   1 should expect that if an
account were to be furnished of the
respective ages at which vaccination
had been performed in any given num-
ber of cases of failure, that the fre-
quency of failure would correspond
with the earliness of vaccination.

If these premises should prove cor-
rect, the observance of the regulations
issued by the parish authorities will
tend to prevent the occurrence of
small-pox during infancy only, but
greatly to increase the number of
failures which will occur at later
periods.   For the poor will not be
much disposed to take their children
to be vaccinated a second time; in
short, the instances of small-pox occur-
ring after vaccination, whether it had
been performed too early or not, have
been so numerous, that the majority of
the poor have lost their confidence in
vaccination as a preventive of small-
pox.   Government should, therefore,
have provided that they should, as well
as the surgeon, receive a gratuity on
each occasion; which gratuity, how-
ever small, would have proved a much
more effectual means of securing a

general vaccination of the poor children
of this kingdom than the plan about to
be adopted.—I am, sir,
              Your obedient servant,
                      HENRY S. SEARLE.
Queen's Place, Kennington Common,
        Nov. 18th, 1840.

ERGOT—RUPTURE OF UTERUS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case
of sufficient interest, I should feel
obliged by its insertion in your valu-
able periodical.—I am, sir,
              Your obedient servant,
                      GEORGE COWARD.

London, Nov. 19, 1840.

A poor woman having been in labour
for some hours, and the pains, although
regular, not effectual, the midwife
who was in attendance, without regard
either to the dilatation of the os uteri,
or the condition of the soft parts gene-
rally, administered a powerful dose of
the secale cornutum, from impatience,
unguided by judgment.   The medi-
cine, after the usual interval, produced
most rapid and violent contractions.
And, as in this case, extreme rigidity
of the os internum existed, the main
force of the uterine contraction was
expended on the womb itself.   Now
the uterus for some time sustained
uninjured this violence and intensity
of action; but, after some time, pros-
tration succeeded to excitement.   The
pulse became rapid and feeble; the
skin cold, and covered with a clammy
perspiration; the features collapsed,
and the countenance expressive of
anxiety; the uterus had given way,
a thinning having existed opposite the
promontory of the sacrum, as post-
mortem examination ultimately proved.
The gentleman with whom I resided
was summoned at this stage of the
case by the midwife.   He found her pale
and moribund; and, in fact, she expired
almost immediately on his arrival by
the bed-side.   On post-mortem exami-
nation, a large irregular lacerated open-
ing, extending somewhat transversely,
was found at the lower and posterior
part of the uterus, originally formed by
its neck : the child lay in the cavity
of the abdomen, which also contained
a few ounces of blood.

REMARKS.—The phenomena of the foregoing case must clearly prove, to every unprejudiced mind, that ergot is capable of acting immediately on the uterus, and that with great violence, not simply " by influencing the imagination :" how else can we explain the severity of the uterine action which I have alluded to ? so violent, indeed, as to lead to its rupture, and the fatal consequences. That the ergot, when administered with proper judgment and precaution, is an invaluable remedy, in want of action in the uterus, when no mechanical obstacle exists, appertaining either to the mother or the fœtus, is now pretty generally acknowledged. This point needs no further comment. I shall terminate by saying, that its action is frequently violent, and should, therefore, be avoided in all cases where existing circumstances do not absolutely demand obstetric interference.

CIRCULATION WITHOUT RESPIRATION.

To the Editor of the Medical Gazette.

SIR,

CONCEIVING the following case to be an unusual one, and not devoid of interest, I take the liberty of communicating it for insertion in your journal.

I am, sir,

Your obedient servant,

ROB. GORTON COOMBE.

15, Great Marylebone St.

CASE.—William Blake, æt. 60, on Wednesday, October 14th, was taken suddenly ill whilst at work. I saw him immediately, and found him insensible. *His respiration had quite ceased.* His extremities were warm, and not at all paralyzed, but now and then they were slightly convulsed. His eyes were fixed and glassy. The external jugular veins, and all the superficial veins of the head and neck, were greatly distended. His countenance was livid, and the tongue slightly protruded. When I first saw him the action of his heart was uninterrupted, and continued to beat with energy for ten minutes. After this it continued its action, but with less energy, for twenty minutes, being at one time very distinct, and at another almost imperceptible, until, at the expiration of three quarters of an hour from the first time I saw him, the action of the organ became imperceptible both to the hand and ear. Mustard poultices were applied to the calves of the legs and epigastrium, and other remedies were ineffectually resorted to.

An autopsy discovered a ruptured vessel at the base of the brain, from which a quantity of blood had escaped even to the distension of the lateral ventricles.

REMARKS.—The continuance of the heart's action in this case, for so long a period after the function of respiration had altogether ceased, is very remarkable. In cases where persons have been attacked in a manner similar to this, and where post-mortem examinations have exhibited effusion of blood in the brain from a ruptured vessel, I have observed the heart's action to have ceased in a few minutes after the function of respiration was arrested; and in no case am I aware that the heart continued to pulsate for so long a period as in the present instance. The quantity of blood which the lungs contained at the time that the respiratory movements were put a stop to by the compression of the brain and medulla oblongata, and the constant supply of blood derived by the heart from this source, doubtless acted as a stimulus to that organ, exciting its contraction so long as the supply was afforded, and as this supply became less, so did the contractions of the heart become more feeble, until they finally ceased.

On looking over an interesting article in the Cyclopædia of Surgery, by Mr. P. Bennett Lucas, on the " Theory of Asphyxia," I find that the arrest of the circulation first takes place in the capillary vessels of the lungs : therefore the long-continued supply of blood which the heart in this instance received must have been derived from the larger pulmonic trunks, and from the venous trunks of the system generally; and the quantity of venous blood in this patient's body would be considerable, from the circumstance of his being a robust man, and from none of that fluid having been taken away by venesection; thus corroborating Mr. Lucas's views on this subject, viz. that the heart will continue to beat as long as it receives a sufficient supply of even venous blood.

From the convulsions of the extremities which occasionally manifested themselves during the attack. I conceive that the facts of this case likewise confirm the opinion of Dr. Kay, (quoted in the above-named article) in opposition to the theory of Bichat, viz. that venous blood " is capable of exciting, instead of destroying, the contractility of the muscles."

PUERPERAL CONVULSIONS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the following case of puerperal convulsions worthy of a place in your valuable journal, I shall feel obliged by your inserting it.

I am, sir,
Your obedient servant,
JAMES KIRK.

405, Gallowgate, Glasgow,
Oct. 28, 1840.

October 18th, 1839, 8 A.M., was requested to see Mrs. G——, a fine healthy young woman, in the ninth month of her first pregnancy, who was said to have fallen suddenly into a nervous state at seven this morning. On inquiring if any cause could be assigned for this state, learned that she had been alarmed during the night by a cat which had concealed itself in her bed-room. On arriving, found patient in bed; insensible; pulse quick, but becoming slower every time it is felt; pupils dilated; breathing performed with a snoring sound; distortion of the countenance, and convulsions of the whole body; does not answer when spoken to. In fact, carus with convulsions.

> Fiat venesectio ad ʒxxiv.; et habeat statim enema cum Ol. Terebinth. ʒj. et vitello ovi unius. Lotio frigida capiti capillis prius abscissis.

10 A.M.—No better; only one stool from injection; has had nothing resembling labour pains; *os uteri* cannot be felt on examination.

> R Sub. Mur. Hyd. gr. v.; Pulv. Scammon. gr. ij.; Pulv. Gambog. gr. j. M. Sumat statim.

4 P.M.—Convulsions gone; coma still present. Continue cold lotion to the head.

> Sinapismata pedibus.

19th — Still comatose; convulsive jerking of left leg and arm.

Repetatur venesectio ad ʒxij.

Patient attempted to seize the lancet, being the first sign of consciousness she had given since commencement of illness; continue cold to head, and repeat sinapisms to feet.

20th.—Much better; no coma; no convulsions; has been able to take a little tea and toast for breakfast; answers when spoken to; complains of pain of head; belly much smaller from descent of the uterus. Shave the head and cover it with a sinapism; (this, however, was not done till the following day:) to be sent for when labour commences.

4 P.M.—Has been in labour for some time; uterus and vagina laid into one continuous passage; head presents; puffy tumor of scalp; bones of cranium widely separated.

6 P.M.—Labour just concluded; child still, as was to be expected; placenta did not follow readily; patient incoherent. To be well watched. Both fœtus and placenta seemed healthy.

21st.— Neither coma nor convulsions, but they have been succeeded by puerperal mania, for which the head was shaved, and a sinapism applied over the whole scalp; this was followed by a blister to the nape of the neck, and the use of the camphor mixture, while sleep was procured by a draught containing hyoscyamus. ether, and valerian. Under this treatment she recovered so well as to be able to be sent to the country a fortnight after confinement.

MEDICAL GAZETTE.

Friday, November 27, 1840.

FARTHER INVESTIGATION RESPECTING THE DEATH OF ELIZABETH FRIRY.

THIS remarkable case continues, and very deservedly, to be the subject of inquiry. The question, as far as regards poor Friry herself, is one of the most painful interest. Was her death merely

hastened by neglect, and her last hours embittered by those who should have afforded her relief, or did she die of actual starvation? But when we ask how many more victims may have been offered to the Moloch of economy — when we consider how many of these wretched outcasts may sleep in the cemeteries of England, their fate scarce known beyond the boundaries of their parishes, and but whisperingly commented on by those who are destined shortly to follow them, it is hardly possible to over-rate the importance of the investigation.

Every one, in fact, that feels the innate consequence of the present inquiry is enhanced by its being a key to hundreds of suppressed cases. The New Poor Law, like the deadly Manchineel-tree, scares away those who would ascertain the fate of its victims; and our curiosity is thus increased to hear the disclosures of the bold few who have penetrated its mysterious shade.

Without imagining a coroner to be much worse than other men, we may easily suppose him to be reluctant to hold inquests in cases of death from starvation. The mere holding of such an inquest is more than a half censure on Boards of Guardians and other comfortable people, who in old English were called "men of worship," and in the slang of the day, are "respectable." But the censure is doubled if we suppose the coroner to issue his warrant for the disinterment of the emaciated corpse, already hurried into its grave. The dismal spectacle is a reproach to the authorities; and before the verdict has been returned they are obliged to confess, like the king in Hamlet,

> "We have done but greenly,
> In huggermugger to inter him."

Now, the coroner may be an attorney, with six children. and a great desire of drawing up more leases: is it too depreciating a view of human na-

ture to suppose that he will lean to the side of those who prescribe, rather than to that of the men who drink, the water-gruel: that he will endeavour to persuade himself that dietaries can scarcely be too spare, or relieving officers too austere? Let us rejoice, therefore, that the case of Elizabeth Friry has been so repeatedly investigated, and so amply reported, as to afford instruction to the Poor Law authorities throughout England, and to show them, in the words of Sir E. Head, that the manner of officers of unions to the poor, and the regularity of attention to and attendance on them, are as much to be considered as the quantity and quality of what they receive. Another lesson taught by Sir Edmund is, that " the rule in all unions over the kingdom is, and the Poor Law Commissioners wish it to be understood as such, that in common cases it is necessary for a medical order to be obtained first, but in urgent cases medical officers are not to wait for that." *

It certainly savours of the curious, that the Commissioners should have kept their Poor Law school so many years, without being able to teach their pupils this elementary point; but so it is. A Board of Guardians shall show itself *cereus in vitium flecti ;* it can learn the art of making gruel of such singular attenuation. that between that and water nothing lives; but to learn that urgent distress requires instant succour is a lesson too hard; and the Board still has to master the alphabet of charity after five years' schooling. As a striking example of this deficiency, we may mention the case, on which we slightly touched in our last number, of Ann Griffin, the woman who was lately delivered in a cab. This poor deserted creature was driven, while in labour, first to a house in Gerrard Street, next to the Westminster Hospital, then to

---

* Times, Saturday, Nov. 14, 1840.

Queen Square, a "doctor's shop" in Tothill Street, the lying-in hospital in York Road, Lambeth Workhouse, St. James's Workhouse, King's College Hospital, the station-house in Bow Street, and finally to St. Giles's Workhouse, where she was taken in. The investigation into her case took place on the 13th of this month, at Lambeth Workhouse, before Sir Edmund Head. Several members of the Board of Guardians were present, and took part in the proceedings. It appeared that during the absence of Mr. Adam, the master of Lambeth Workhouse, Mrs. Franks, the matron, did not admit Ann Griffin, not knowing her case to be an urgent one. From the circumstances under which the miserable woman was brought there, this seems possible ; but mark, reader, what follows :—

Commissioner : " I have merely to inquire into the conduct of the officers of the Union. I think, however, as the general order from the commissioners is to give relief in all cases of necessity, that the master ought to be examined as to that fact."

Another guardian was aware that relief was ordered in all cases of urgent necessity, but still, if it were generally known that relief was afforded in such cases, the parish would be inundated with them.

The Commissioner knew that the instructions from the Poor Law Commissioners were to that effect ; in fact, it was the law of the land.

A discussion then ensued between the guardians as to whether the master should be examined, *some of them fearing that if it were generally known that such cases were admitted a great evil would arise**."

Sir Edmund, however, pressed the examination, and Mr. Adams, being called in, read an extract from the rules of the Poor Law Commissioners, setting forth the modes in which paupers may be received into the workhouse. The first and second are, by

* Times, Nov. 14, 1840.

order of the Board of Guardians, or by a provisional order, signed by an overseer, churchwarden, or relieving officer ; and the third is " *by the master of the workhouse, without any such order, in case of any sudden or urgent necessity.*"

This last is the fatal secret, the " open Sesamé !" to the workhouse doors, which those economic guardians were so unwilling to publish ; the rule, it seems, is bearable enough, provided it is kept snug ; but once let it be spread abroad, and all the world will rush to enjoy the rich slices of Lambeth bread washed down with those tempting draughts of Thames-water. But let the board be comforted : supposing the rule to be advertised and noised abroad by those odious newspapers, the rush will be equalized, and their parish will only obtain its aliquot part. Or, if we suppose Lambeth to be dangerously attractive, and their splendid oatmeal to bear away the bell from St. Marylebone, St. Pancras, and St. Martin, it will be easy to compensate this *dono infelice di bellezza* by enacting that when one union receives the urgent cases which belong to another, the expense shall be repaid.

Up to the moment of our writing we have not heard of any steps taken by the Commissioners to supply this evident defect in the present practice ; perhaps, like the Lambeth Guardians, they are staggered at the " great evil" which would arise, if the poor knew that they need not lie-in in the streets.

Let us now return to Elizabeth Friry.

We observed in our last number, that the investigation held before the Board of Guardians of the Kensington Union, terminated, like the inquest which had preceded it, by a censure on the surgeon and relieving officers of the Union. The Poor Law Commissioners, probably, felt themselves wounded through the sides of their servants ; they knew that an Act of Parliament, however

harsh in its intent, is but a dead letter; it is the spirit in which it is worked which gives the law its fatal vitality. The Commissioners are naturally desirous to show that the act works well ; that it lowers the rates, without starving the poor, and, accordingly, they ordered a third investigation.   It took place last Friday, the 20th inst. and was conducted by Dr. Kay, and Sir E. Head, Assistant-Commissioners.   It is reported in the Times of Saturday, November 21st.

Its object was to show that Friry had not died of starvation.   The truth is, that in almost every case it is difficult to prove that a person has died from simple starvation, and the difficulty was increased in this instance by the disinterment not having taken place till a fortnight or more after the burial.   Dr. Alison, who speaks from experience, assures us that life may be supported for some time on three meals a week.   Suppose a woman with some of the infirmities which sixty-five years seldom fail to bring with them, dragging on her existence in this manner for two months, with just food enough to excite appetite rather than to satisfy it, sleeping on the boards, with scanty clothing, deserted by hope and energy ; what logician, or what pathologist, shall decide the exact share which each destructive influence had in extinguishing the last spark of life ? It is quite clear that Elizabeth Friry was a neglected and ill-used woman; but whether food was more essential to her recovery than a bed, or a bed than food, would be hard to determine ; she ought to have had both.   Few candid persons, however, would pour out all their anger on the mere instruments in this case, and let their masters go free : when we hear of Egyptian revenues extorted by the scourge, we do not expend our indignation on Hassan and Selim, who wield the rhinoceros skin, so much

as on Mehemet Ali, who sets them at work.

Dr.   Kay's cross-examination of Mr. Wildbore, the surgeon who performed the post-mortem examination, was ably conducted ; though, in truth, such scrupulous doubts would scatter into the air half the supposed facts of morbid anatomy.   Elizabeth Friry died of want of food, in Mr. Wildbore's opinion ; and he reasonably concludes this to have been the cause of death, from the extreme emaciation of the body, unaccompanied by organic disease.   But then the brain was decomposed, and could not be examined ; so that it *might* have been affected by an organic disease, which *might* have produced the attenuation.   As far as we know, however, organic disease of the brain is rarely attended by extreme emaciation.   Only a part of the thoracic aorta was examined—an omission of some importance in a dissection which ought to have been so critically minute.

If an immediate cause of death were sought distinct from the want of sustenance, it might be found in the leg of the deceased, which had swollen to the size of a man's thigh.   It burst the night before she died, and discharged a wash-hand basin-full of serum.

As to the frightful destitution of Elizabeth Friry, there is no doubt whatever.   The clearest evidence on this point is that of Catherine Ryan, the indigent and benevolent friend who gave Friry shelter, when all society seemed to have conspired against her.

ROYAL COLLEGE OF SURGEONS.

MR. LAWRENCE has been elected into the Court of Examiners in place of Sir A. Carlisle ; and the vacancy which that gentleman's decease caused in the Council of the College is now filled by Mr. Liston.

PETITION FOR MEDICAL REFORM.

To the Editor of the Medical Gazette.

Sir,

I beg to forward a copy of a Petition for Medical Reform signed by the medical practitioners of Reading, and intrusted for presentation to the Marquis of Normanby and Serjeant Talfourd. Copies have also been forwarded to Mr. Warburton, and to the members of Parliament for the town and neighbourhood.—I am. sir,

Your obedient servant,
Charles Cowan, M.D.

To the Right Honourable the Lords Spi-
ritual and Temporal of the United
Kingdom of Great Britain and Ireland,
in Parliament assembled.

The petition of the undersigned medical practitioners residing in the Borough of Reading, in the county of Berkshire, and the vicinity thereof,

Humbly sheweth,

That your petitioners have long deplored the evil consequences ensuing not only to their own body, but to the community at large, from the want of an adequate legal constitution for the Medical Profession in Great Britain and Ireland.

That the laws which have been enacted from time to time, for the regulating of medical affairs, and the institutions to which have been committed their direction and management, have been alike insufficient to guard the public health, or to suppress the pernicious practices of ignorant pre-tenders to medical and surgical knowledge : that impostors of every description are, con-sequently, allowed to prey upon society ; and empiricism, in its most aggravated forms, is suffered to pursue an uninterrupted and most dangerous career, to the detriment of the public safety and the scandal of a great and civilized empire. Throughout the United Kingdom, any individual is, moreover, at liberty to dispense medicine of every descrip-tion, and to sell the most deadly poison without supervision or control.

That the Corporate Institutions, which at this time preside over the medical profession, are wholly unequal to the correction of its manifold abuses. Under their existing con-stitutions, they are incapable of promoting the physical well-being of the people, and are unable either to enforce the examination of candidates for medical practice, or to defend the duly qualified practitioner against an unjust usurpation of his privileges on the part of uneducated and unauthorized com-petitors.

Your petitioners, therefore, pray, that your Honourable House will adopt such measures as to your wisdom shall appear best calculated to confer upon the medical profession a sound and efficient legal organi-zation, and place it under a system of govern-ment, based upon principles which may protect the interests of its members, and promote the public welfare.

And your petitioners, as in duty bound, will ever pray, &c.

QUESTIONS ON MEDICAL REFORM.

To the Editor of the Medical Gazette.

Sir,

The writer will feel much indebted to any gentleman who will favour him with answers to the following questions :—

Supposing that the friends of transcen-dental reform had succeeded in obtaining an act of parliament for the formation of a me-dical council in each of the three metropoli-tan cities, and a senate in London, of whom would the members sent by the medical commonalty consist ? Who would be the president of the senate ? What objects would engage the attention of these bodies ? What would be the fate of the existing medical corporations ? Would the members sent to the councils by the medical commonalty be the calm, the scientific, the experienced in practice, the pure in character ? Or would they be those who were the most bustling, most ready in speech, most lavish of pro-mises, most successful in canvassing ? Would the chair of the senate be occupied by some man of high talent, distinguished for science and virtue ; or by a clever politician who had found the medical profession too narrow a field for his exertions ? Would the coun-cillors from medical corporations, and those sent by the commonalty of the profession, cordially unite in promoting the same object, or would they form two opposing forces compensating each other, and causing the machine to stand still ? Would the duties of the councils consist in refining on the mi-nutiæ of medical education ; in granting licenses to candidates for practice ; in com-posing professional quarrels, and visiting with their displeasure unprofessional conduct; in prosecuting those accused of malapraxis, and suppressing quackery ? Would the me-dical councils endeavour to accomplish this last object by encouraging popular lectures on physiology and medicine, and by increasing the requirements for obtaining licenses to practise ? Would they ultimately find that by raising high the scale of all medical edu-cation, and thus diminishing the number of practitioners in the lower walks of the pro-fession, they had unintentionally delivered over all but the wealthy classes into the hands of druggists and quacks ? Under the new regime would the medical corporations re-main without performing any active duties,

enjoying those funds which some might think far better bestowed on the newly created and energetic bodies ; or would they be allowed to continue examining and granting licenses, which, however, should be of no avail without the confirming approval of one of the medical councils ?   A REFORMER.

MANAGEMENT OF LUNATICS.

To the Editor of the Medical Gazette.

SIR,

I HAVE just been reading the report of the Middlesex magistrates, as published in the *Times*, and have been not a little surprised at the statements therein made in reference to the question of restraint or the non-restraint system in the management of lunacy. Apart from the prevention of mania there can be no subject which demands more searching inquiry than the treatment of the insane ; but I cannot help thinking there is much ado about words instead of actions. It may please the fine feelings of sympathy to state to the world in this or that asylum the non-restraint system is followed, but to the practical man it is all sheer nonsense : why send a poor creature away from the endearments of home if such a mild plan of operation would be safe ? The question is not whether patients shall be bound by iron, wood, or leather ; but it is, how are patients who possess not the rational will, to be *made* to undergo a proper mode of treatment ? It is a standard principle in the treatment of lunacy never to threaten without performing : therefore, it is necessary to have power to act, and not to depend upon imperfect means. *Mechanical as well as medical treatment is necessary* in the treatment of mania. Suicide is not the crime to be dreaded in the violent maniac : it is the quiet hypochondriac who requires watching : he is generally artful, and unsuspecting : distress is marked in his countenance, and he feels the indescribable pain of horror which in a moment impels him to the dreadful act ; therefore, mechanical restraint is not employed solely for the purpose of preventing self-destruction, but to prevent the patient during a paroxysm of excitement from injuring either himself or another ; and also to enable the practitioner to administer medicaments so as to tranquillize the nervous system. It cannot be denied that cruelty has been inflicted on these poor people for the purpose of saving labour and watching. It is no ordinary task to take the charge of a maniac, and, if those who have advocated the self-styled non-restraint system have in any way been the means of increasing the number of attendants on the insane, they have conferred a great boon. It cannot be denied that in some cases it is almost impossible to keep the patient clean, and pro-

bably it is the injudicious mode of rendering a patient cleanly that constitutes one of the flagrant defects in the treatment of insanity. There is another cause which too frequently irritates the temper of the keeper, and that is, the resistance on the part of the patient to take food. I have known a patient resist both solids and fluids for five days, and then refuse, to as to render it necessary to compel him so take liquids by pouring them through a funnel down one of the nostrils. Humanity pleads for mildness in the treatment of the insane, but humanity never should interfere with duty.

In conclusion, I would again plead for the necessity of preventing so direful a malady. Let the subject be but better understood by the profession, it would afford us no inconsiderable revenue, and greatly enhance the character of the medical man.

I remain,
Yours most respectfully,
JOHN GRANTHAM.

Crayford, Kent,
Nov. 16, 1840.

AXIOMS FOR THE DEAF.

To the Editor of the Medical Gazette.

SIR,

I WAS in the act of sketching out the following axioms for the deaf, when the current number of your meritorious periodical was placed before me. By a singular coincidence it contains a communication strikingly illustrative of the importance of more than one of those axioms. The idea instantly occurred to me to forward them to you. To remove existing errors in the *professional and domestic* treatment of deafness is one of the leading objects of my life ; and, with the hope of your co-operation in the present instance, I have the honour to subscribe myself

Your obedient servant,
JAS. YEARSLEY.

29, Sackville Street,
Nov. 21, 1840.

1. Never syringe your ears, nor allow it to be done by others, unless for the removal of an accumulation of wax.

2. Be sure that such accumulation forms an obstacle to the transmission of sound, otherwise it had better remain where it is, for it should always be borne in mind, that the wax is a natural secretion placed in the passage of the ear for a specific purpose. Its presence, in moderate quantity, indicates a healthy condition of the outer passages of the ear. Its absence is the effect, and not, as is generally supposed, the cause of the disease which produces the deafness. Like deafness, want of wax is only a symptom of ear disease ; hence the absurdity of attempt-

ing its restoration by stimulating drops and ointments.

3. Never pick the ears.

4. Never wet the hair, nor wash the head with cold water. A most pernicious practice !

5. Never bathe, nor use a shower-bath, without protecting the head and ears. Even then I question its propriety.

5. Never attempt to stop a discharge from the ears but under proper advice ; for it may be that the drum of your ear is open, and then, the employment of a stimulating or astringent injection will risk even fatal consequences.

7. Never apply, nor suffer to be applied, any thing to the outer passages of the ears, which causes heat or pain. Such applica- tions may prove of temporary benefit, but when the stimulus has subsided you will be left worse than before.

8. Be strict in diet. Stomach derange- ments are a prolific source of deafness.

9. Never expose yourselves to wet or windy weather.

10. Never consult an aurist who is not an educated and diplomatised surgeon, and who does not admit that deafness is an in- firmity often difficult of removal, and often, very often, incurable.

ABERDEEN INFIRMARY.

CASE OF STRANGULATED HERNIA.

A. R., thirty-one years of age, a sailor, was admitted on the 9th of August, 1839, with symptoms of strangulated hernia. He has had inguinal hernia of the left side for two years, but never wore a truss. The rupture often came down while he was working, but he was able to return it himself by lying down on his back ; and experienced little inconvenience from it till of late, when it has never been completely reduced. He suffered a severe fall about three o'clock yesterday afternoon, and a piece of wood struck the tumor, which immediately came down to a very large size. He was obliged to be car- ried home, and passed a night of great suffering, from twisting pain round the navel, and in the tumor. Vomiting came on early this morning, and he was brought to the hospital at half-past eleven o'clock. Pulse now 108, full and strong ; tongue foul, but moist ; frequent retching, and bilious vomiting. Bowels not moved since yesterday morning : much pain and tenderness of the abdomen on pressure. The taxis was perse- veringly tried, but without success ; the bulk of the tumor seeming to be partially dimi- nished at first, but obstinately resisting further reduction. He was then put into the warm bath, and while there thirty-two ounces of blood were abstracted from a large

orifice. During the faintness thus produced the taxis was again tried, but in vain. He was then removed to bed, and a bladder filled with pounded ice was applied to the tumor. A purgative enema was ordered to be immediately injected, and if it should have no effect, a turpentine enema two or three hours after.

8 P.M. No effect from the injections. Vomiting and pain of abdomen continue, with much tenderness and tension : pulse 108 ; tongue dry. A consultation being held, immedate operation was agreed on ; but to this the patient positively refused to submit till he should see his friends, who lived at a considerable distance. An express was accordingly sent for them, but in the mean- time it was resolved to try the tobacco enema. One dram of tobacco was therefore infused in a pound of water, and one-half immediately thrown up. As this produced little effect, at the end of half an hour the remainder was injected. This produced slight faintness, and the pulse became more feeble ; but the injection came off without any fæculent matter.

August 10th.—7 A.M. Has passed a rest- less night, with frequent vomiting, and occa- sional slumbering ; pulse 110 ; abdomen tense and tender, and the tumor hot and painful. The operation being still thought admissible, and the patient consenting to it at the advice of his friends, I proceeded to perform it immediately. The several tissues were found remarkably distinct, not being so much agglutinated by adhesion as they are often found to be. On opening the hernial sac a considerable quantity of fluid escaped. The sac was found to contain a large quan- tity of intestine, much distended, but no omentum. The coats of the intestine were much congested, and of a dark brownish red colour, with some patches of a brighter red. The external ring was found to admit with little difficulty the point of the finger. It was, however, slightly dilated upwards, by the bistoury introduced on the finger, after which the finger passed readily into the abdomen. Reduction was then commenced, and went on easily for a short time ; but the gut in the lower part of the tumor was found to be very tense, and its contents could not be pressed up. On examination, a liga- mentous band was found attached to the mesentery, and tightly surrounding a turn of the intestine five or six inches in length, which was very tense, and of a darker colour than the rest. The point of the little finger was with difficulty inserted between it and the gut, and the band was divided by a narrow bistoury. The whole of the intestine was then gradually returned, and the opera- tion was concluded in the usual manner ; the integuments being brought together by two stitches, and by adhesive straps. An injec-

tion was ordered on his removal to bed, and at 10 o'clock six drams of castor oil were administered.

2 P.M. He has had several very copious fæculent stools ; vomiting has ceased ; pulse 102. He is ordered to take, every two hours, two ounces of infusion of senna with cream of tartar.

8 P.M. Complains of considerable pain and tenderness of the abdomen ; skin hot ; pulse 112. He was therefore bled to twenty ounces, and a pill of five grains of calomel and one grain of opium ordered, to be followed in the morning by the infusion of senna as before..

August 11th.—He has had several very copious motions ; pain and tenderness of abdomen much diminished ; pulse 96. From this time he went on in the most favourable manner. The bowels were kept open by castor oil and the infusion of senna alternately. A considerable part of the wound united by the first intention, and the remainder granulated favourably. The cure, however, was retarded by the wound assuming an inflamed and irritable appearance about the twelfth day, followed by partial absorption of the granulations. This seemed to be owing to the state of the air, as erysipelas and sloughing phagedæna were prevalent in the hospital at the time. Poultices and water dressings were ordered, with nourishing diet, four ounces of wine daily, and one grain of opium at night. Under this treatment the sore gradually improved, and on the second of September had again begun to cicatrize. On the twentieth it had completely healed. He was dismissed a short time after, with orders to wear a truss to prevent a return of the hernia. He has since performed several voyages, and returned well.

This case suggests a few observations. The stricture seemed to be formed solely by the ligamentous band, the external ring being wide enough to have admitted of the return of the intestine, if it could have been completely emptied of its contents. The manner in which this band was formed can only be a matter of conjecture, but it seems probable that it was at first merely an adhesion between two neighbouring points of the mesentery, by effusion of coagulable lymph, which had gradually been elongated, and then a loop of the gut had passed through it, and been arrested there. At what period this happened is uncertain ; but it may probably have occurred at the time when the hernia first became irreducible. At all events it must have existed for a considerable time, as the part of the intestine embraced by the band was evidently narrower than the rest, and also of a whiter colour and firmer texture. The most important circumstance in this case, however, is its bearing on the question so much discussed, of the propriety of re-turning the hernial sac unopened. If this had been done in the present instance, which probably might have been accomplished by dilating the ring a little more, the intestine would still have been in a state of strangulation, and the patient must have died in a few hours.

CASE OF FUNGOUS CARCINOMA.

M. A., ætat. 30, mother of a family, admitted May 27th, 1839. About eight years ago she first observed a small tumor near the temporal ridge of the frontal bone, which ulcerated, and bled freely when it received any injury. It has been often touched with caustic, but continued gradually to increase. Within the last six months its increase has been much more rapid. It is now about the size of the half of a very large orange, but somewhat oval in shape, being three inches long by two and a half broad. Its surface is irregular, red, ulcerated, and of a cauliflower-like appearance ; its texture firm, and somewhat warty, and it discharges a large quantity of sanies. She complains of a burning sensation, with occasional darting pains in it ; health good, except incidental headaches. On account of its large size, bread base, and close connexion with the cranium, it was considered very unfit for excision by the knife. It was therefore determined to attempt its removal by chloride of zinc.

On the 3d of June a layer of paste, formed of one part of chloride of zinc to three of flour, and about the thickness of a crown-piece, was applied to the most prominent part of the tumor, so as completely to cover more than one-half of it. It produced considerable burning pain, but a dose of T. Opii rendered it quite tolerable. At the end of four hours the paste was removed, and a poultice applied.

On the 5th a large white eschar was found to be formed, and beginning to separate, with little surrounding inflammation ; and both the bulk and pain of the tumor were much diminished. A similar layer of paste was applied to the remaining part of the tumor.

12th.—Some portions of the tumor, which had escaped the action of the chloride, have been successively covered with the paste. The sloughs are not yet wholly separated, but the tumor is much reduced in size, and the pain almost gone.

June 17th.—The whole tumor seems to be destroyed, except two or three small overhanging edges, which appear to have been protected by the integuments. One of these was removed by the curved scissars, and the rest touched by potassa fusa. The granulations look healthy.

26th.—All the sloughs are now separated ; the granulations are healthy, and cicatriza tion is proceeding regularly from the circum-

ference towards the centre. The sore is occasionally touched with nitrate of silver.

July 4th.—Cicatrization advancing ; but, as some of the granulations appeared rather unhealthy, they were destroyed by the paste.

13th.—More than three-fourths of the sore are now firmly cicatrized ; and the re- mainder looks healthy, and level with the surrounding integuments.

August 3d.—The sore has now been com- pletely healed for several days, and the cicatrix is level and quite natural.

A case in many respects resembling the above, which occurred at the Hôpital de la Pitié, in Paris, is related in the Gazette des Hôpitaux, 23 Fevrier, 1840. It is called by M. Lisfranc " Tumeur carcinomateuse, avec ulceration phagédénique." Aware of the disadvantages of excision in such cases, on account of the difficulty of obtaining a cicatrix without great deformity, from the deficiency of cellular tissue, and the habitual state of tension of the integuments, M. Lisfranc adopted " a mixed method of treat- ment," consisting of repeated cauterization alternating with the application of leeches, with the view of destroying the diseased parts, and at the same time favourably modi- fying the action of the surrounding tissues, and this treatment was " crowned with the most brilliant success." In the case of M. A. the chloride of zinc seemed to fulfil both these intentions ; entirely eradicating the diseased parts, and exciting in the sur- rounding tissues only such a degree of inflam- mation as contributed to the formation of healthy granulations, and the filling up and cicatrization of the wound. In cases of this kind the chloride of zinc seems to me to possess great advantages over all other escharotics, even arsenic itself, in the facility with which its action can be limited to the diseased tissues, and the very favourable modification which it produces in the action of the surrounding parts ; ulcers produced by it healing in a shorter time than those produced by any other means. This I have repeatedly exemplified in carcinoma of the integuments of the face ; which, when situated where the wound cannot be drawn together by stitches, is very unfavourable for the operation of excision, but which I have in many instances succeeded in curing completely, and with very little deformity, by the use of this escharotic.

ON OPHTHALMIA NEONATORUM.
By Dr. P. G. Cederschjöld.

In order to ascertain whether the purulent ophthalmia of new-born infants is caused by a discharge from the genitals of the mother, which affects the eyes of the child during birth, Dr. Cederschjöld had the question put to every woman delivered during the

year 1832 in the general lying-in hospital at Stockholm, whether or not she had such a discharge. Three hundred and sixty women were delivered ; and subtracting those who bore dead children, or whose children died a few days after birth, there remained 328. Of these, 137 had a discharge from the geni- tals, and 181 had not. Thirty infants had purulent ophthalmia ; namely, 20, whose mothers had a discharge, and 10, whose mothers had none. Hence it appears that discharges from the genitals are extremely common among pregnant women ; that women may be afflicted with them, without giving their offspring ophthalmia purulenta ; and that children may have the disease, though the mothers have no discharge ; a proof that the malady may arise from other causes. But when we consider that of the children born of mothers affected with a discharge, 20 in 137, or about 1 in 6 [more nearly 1 in 7], suffered from the ophthalmia ; while only 10 in 181, or about 1 in 18,- of those whose mothers were unaffected, had the ophthalmia, and that, therefore, the pro- portion of the former was [nearly] three times as great as of the latter, we may assume, *that a discharge from the genitals of the mother, though not the sole cause of this disease, is a very frequent one.—Zeitschrift für die gesammte Medicin,* from a Swedish work.

PURE TANNIN A REMEDY FOR EXCESSIVE PERSPIRATION.
By Dr. Charvet.

Sweating is a morbid symptom which is often so serious and inconvenient, that the practitioner is obliged to combat it by spe- cial remedies. The acetate of lead, which has been extolled of late years, sometimes causes inconveniences which hinder many practitioners from employing it in cases where its use seems clearly indicated. Pure tannin, employed as an anti-sudorific, ap- pears to be free from these disadvantages. The author has employed it for two years at the hospital, and in his private practice, and though it has not succeeded in every case, it has in almost all.

He prescribes it in the form of pill, and in the dose of from two and a half to ten cen- tigrammes (half a grain to two grains) in twenty-four hours, generally in the evening, with or without opium, which neither checks nor favours its action. The first time he ad- ministered it was in the case of a phthisical patient, who was already in a state of maras- mus, and whose cough, fever, and oppressed breathing, were less troublesome than the general perspiration with which he was inundated every night. The patient asked for some medicine against the perspiration,

which he considered the sole cause of his sufferings, and was ordered twenty-seven milligrammes (about three-fifths of a grain) of tannin. The next morning he said he had passed a good night, and hardly felt moist when he awoke. The repetition of the the same dose every evening was sufficient, during several weeks, to suppress the perspirations entirely; but they returned as soon as the medicine was omitted. The dose was raised to five centigrammes (a grain), and then to eight (1 grain three-fifths), and always with the same success. The author relates several other cases in support of the antisudorific property which he attributes to tannin; they occurred among consumptive patients who had arrived at the last stage of the disease. They are additional examples of the activity with which tannin suppresses sweating, even when the disease from which it arises is beyond the resources of our art. —*L'Expérience*, and *Gazette Médicale.*

RÉMARKABLE CASE OF TAPE-WORM.

MADAME R., aged 37, of fair complexion, and robust constitution, and generally in good health, had experienced, for seven or eight months, a general uneasiness, with a feeling of oppression and weight in the abdomen, principally about the epigastrium. More than once her abdomen became large suddenly.

She commonly had a disgust for food; but sometimes, on the other hand, she was tormented by a voracious appetite, recurring irregularly, and by frequent nausea, without vomiting. Her tongue was white and large, her mouth bitter and pasty. As the patient expressed it, it often seemed as if something pricked or tore her stomach; and she pointed out the epigastrium as the only seat of these very painful sensations. When the patient ran, she felt a substance move up and down in the same region, which she compared to a bladder filled with fluid. There was frequent diarrhœa, and the patient was, at two different times, attacked with very violent convulsions during the night, together with complete loss of consciousness. During the fits, which lasted more than an hour each time, the husband of the patient had great difficulty in holding her; she then fell asleep, and the next morning had no recollection of what had passed.

Mad. R. being requested to examine her stools with attention, in a few days brought a fragment of tape-worm, which she had just passed. The next day she was ordered to take 60 grammes (1200 grains) of the root-bark of pomegranate, in the form of decoction. An hour after taking the first glassful, she suddenly, and at once, passed a considerable mass of tape-worms in a cluster. They were twelve in number, and their length extended to 48 metres.

Since then, all the symptoms which Madame R. experienced have completely disappeared. Her first care was to ascertain whether the motion of the epigastric region which she had formerly felt when running was still perceptible; but to her great surprise she felt nothing of the kind.—*Archives Générales,* and *Gazette Médicale.*

ON THE
LYMPHATICS OF THE BRAIN.
BY F. ARNOLD.

IN his researches on the structure of the brain and spinal cord, and in his Icones Anatomicæ, the author has published the first complete description of the absorbents of the brain. In the dura mater, veins only were for the most part filled by the injection, but he obtained very successful mercurial injections of the absorbents of the pia mater. He distinguishes three different networks: 1st, A superficial delicate one, whose vessels are one-sixth of a line in diameter, and whose meshes are extraordinarily minute, lying in the cellular tissue which connects the arachnoid with the pia mater; 2d, A deeper and coarser network also in the subserous tissue of the arachnoid, and composed of vessels with a diameter of one-fourth of a line; 3d, A still coarser network, with vessels one-half of a line in diameter, and with such narrow interspaces, that when they are filled the brain seems completely covered by the injection. This network, however, is contained in the pia mater, and passes with its plexus into the depths of the furrows between the convolutions. The trunks of the absorbents into which these networks are continued take the course of the veins on the surface of the brain, accompany them closely, and pass with them and with the arteries through the foramina in the skull. In the choroid plexuses of the lateral and third ventricles there are lymphatic networks and small trunks, which collect into one considerable trunk, accompanying the vena magna Galeni. The absorbents of the very substance of the brain, which probably go with its small veins, could not be filled: they always gave way just on the walls of the ventricles. At present also the attempts to inject the absorbents of the spinal cord have had no success.

SPANISH CHOCOLATE.

THE following, according to Mr. Inglis, is the composition of Spanish chocolate:—

"To six pounds of the nut, are added three pounds and a half of sugar; seven pods of vanillas; one pound and a half of Indian corn; half a pound of cinnamon; and a small quantity of musk."—*Rambles in the Footsteps of Don Quixote,* p. 71, note.

CASE OF FATAL HÆMORRHAGE IN AN INFANT.
By Dr. Evert.

The patient was of the male sex, and eight days old ; its mother had been cured of the venereal disease two years before. The child was weak when born, and its arms and legs were affected with a spotty eruption. On the 15th of April, Dr. Evert remarked a small aperture on the under lip, from which blood trickled forth. On the following day, there was very considerable hæmorrhage from the same lip, the navel, and the scrotum. On the 18th, the bleeding from the lip returned. The blood then exuded through the skin, just like the lymph which exudes when the skin is superficially abraded, and it collected in drops upon it. The child died on the 20th.—*Zeitschrift für die gesammte Medicin*, from a Swedish work.

TESTS FOR DRUGS.

Croton oil.—When agitated with its own volume of pure alcohol, and gently heated, it separates, on standing, without having undergone any apparent diminution.

Elaterium [the Extract].—Colour, pale gray : when exhausted by rectified spirit, the solution, concentrated, and poured into hot diluted aqua potassæ, deposits, on cooling, minute, silky, colourless crystals, weighing at least a seventh of the elaterium.

Guaiac [the Resin].—Fresh fracture red, passing to green : the tincture slowly strikes a lively blue colour on the inner surface of a thin paring of a raw potato.

Opium. — A solution from 100 grains macerated 24 hours in two fluid ounces of water, filtered, and strongly squeezed in a cloth, if precipitated by a cold solution of half an ounce of carbonate of soda, in two waters, and heated till the precipitate shrinks and fuses, will yield a solid mass on cooling, which weighs, when dry, at least 11 grains, and if pulverized, dissolves entirely in solution of oxalic acid.

Castor oil.—It is entirely dissolved by its own weight of alcohol.—*Edinburgh Pharmacopœia*, 1839.

[For other tests from the same source, see Medical Gazette, vol. xxiv. p. 932-3.]

RELIEF OF DEAFNESS.

Derham remarks in his Physico-Theology, that the deaf hear best amidst a noise ; for instance, a man hard of hearing heard best when the bells were ringing, and a deaf landlady when the servant was beating a drum.

Hence it is, that as princes and ministers are generally hard of hearing, a noise is made with music, kettle drums, and cannon,

when they pass through a place, in order that they may hear the people better. — *Jean Paul Richter.*

ECONOMY IN LEECHES.

If the hinder part of a leech be cut off before it is applied, it will usually remain on for several hours, the blood constantly dripping away from the wound (like the water from Munchausen's horse). A leech thus treated will suck as much as four others, if too much of the tail have been not taken off, and if the operation be not performed with blunt scissars.—*Dr. Butge*, in *Med. Correspondenzblatt.*—Bd. 9. No. 31.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture XI.

Mortification, as an event of inflammation. Inflammatory fever. Hectic Fever. Typhoid Fever. Modification of inflammation by differences of tissue: Cellular tissue; substance of glands and solid viscera; serous membranes; synovial membranes; tegumentary membranes—skin — mucous membranes; muscular tissue; arteries; veins: substance of the brain.

We were occupied, when last we met, with what may properly be called the *events of inflammation.* We passed in review, 1st, *resolution* as an event of inflammation; 2ndly, *serous effusion;* 3rdly, the pouring out of *coagulable lymph,* constituting the adhesive form or stage of inflammation; 4thly, the formation of *pus,* or *suppuration;* and 5thly, *ulceration.* The pathology of these several events, so far as it is understood, and the change of symptoms to which they may respectively lead, were also treated of as fully as the limits of my course allow. At the close of the lecture I was about to speak of the sixth and last event of inflammation that requires to be noticed; viz. *gangrene, sphacelus, mortification.*

Mortification.—When mortification thus succeeds to inflammation, the part dies; it becomes cold; all circulation through it is at an end; all sensation in it is over. If it be an external part, its colour changes; from being red it becomes mottled, purplish,

679.—XXVII.

green, or black; decomposition takes place; vesications appear, filled with dark-coloured fluids; air is extricated also. If there be a great accumulation of fluid in the part there will still remain tension; but usually the mortified part is flaccid and boggy; and it emits a cadaverous smell.

When *internal* parts mortify under inflammation, they do not always assume this black appearance: often they are yellowish; or the soft tissue of the dead part readily imbibes fluid, and takes the colour of the substances with which it has been in contact. We see sloughs of the mucous membrane of the intestines presenting the ochery hue of the fæcal matters which had rested upon them.

What I have described as mortification, occurring externally, and succeeding to inflammation, is such as the surgeon witnesses. Sometimes it spreads, and loses and confounds itself, insensibly, with the adjoining parts, which still retain life; and which may continue actively inflamed; and subsequently perish also. Under more favourable circumstances, a distinct boundary line is formed between the dead and the living parts; and nature proceeds to amputate the portion which has lost its vitality. The process by which this is effected is extremely interesting: adhesive inflammation constructs a barrier of lymph against any farther advance of the mortification; a furrow of ulceration marks out upon the surface the commencing separation, and (supposing a part of one limb to have become gangrenous, the foot for example) the furrow gradually deepens, until the dead part is completely cut off. This very fact shows that all the textures of the body, skin, muscle, nerve, blood-vessel, and bone, are capable of being removed by the ulcerative process. Meanwhile very interesting changes occur in the part that lives: the large vessels are plugged up, to a certain distance, by the coagulation of the blood contained in them; the coagulation of the

2 C

blood following its stagnation. They are farther sealed up, and the smaller vessels also are closed, by coagulable lymph. Were it not for these changes, fatal hæmorrhage would follow the separation of the dead part. Now this is just what a surgeon rudely imitates when he amputates a limb; he cuts through the parts with knife and saw, and he ties the larger blood-vessels as he goes along. He follows the path which the natural processes point out: and in truth, a great part of both physic and surgery consists in learning what are the expedients of repair and preservation for which provision has been made in the living body; in exciting, or repressing, or directing, or imitating, those natural actions which generally tend, and often suffice, to restore health, and to save life.

Mortification is more common in some internal parts than in others. It is frequent in the cellular tissue; and in the mucous and submucous tissues of the alimentary canal; in the throat, for example, in cynanche maligna; and in the glandular parts of the intestines in fever. It seldom affects the other mucous systems—those which belong to the air-passages and the urinary organs. It occurs sometimes—but not very often— in the substance of the lungs. It is seldom met with in serous and fibrous tissues. It is not at all uncommon in bone; producing *exfoliation* when it is slight and superficial; *necrosis* when the entire shaft of a long bone dies. In these cases the process is slow, and we can watch its repair; and a beautiful process it is: but I must not stop even to admire it.

Now mortification is no certain or constant event of inflammation. It depends, more or less, upon various causes and conditions. Sometimes upon the mere intensity of the inflammation, as in sloughing inflammation of the genitals: the progress of the mortification being fast checked by those measures which are calculated to abate the violence of the inflammation. The sloughing of the cornea in gonorrhœal ophthalmia is another example to the same purpose.

Again, whatever tends to weaken the circulation in the part affected — or in the system at large—tends also to promote the perishing of the textures that are inflamed. In persons who are debilitated by fever, the mere pressure of the body against the bed is enough to produce sloughing of the integuments of the sacrum, hips, and elbows. The same phænomena are apt to occur in parts that are palsied. In dropsical patients, with feeble and impeded circulation, we find that a blister on the extremities, where the circulation is the *most* feeble, will sometimes cause mortification; while it might be applied to the chest without any risk of that event. Probably, in each of these instances, the

unhealthy condition of the blood conduces to the sloughing process. Inflammation of the stomach and intestines is marked by a strong disposition to run into gangrene—and this again is consistent with what I formerly mentioned, of the depressing influence of inflammation of these organs upon the heart.

It is necessary to remember that mortification is capable of being produced by other causes, as well as by inflammation. The death of frost-bitten parts is perhaps scarcely an exception—the phænomena of mortification occur in them after the reapplication of a certain degree of heat—sufficient, probably, to give rise to more action than the frozen parts can bear without perishing. But the mere cutting off the supply of arterial blood, independently of any inflammation, will cause mortification. Ossification of the arterial trunks, and consequent stagnation and coagulation of the blood in them, is the commonest cause of the dry gangrene of old persons—the *gangrena senilis;* which, by the way, is not always dry. In the majority, however, of these cases, the gangrenous part, not being preternaturally loaded with fluid, does not so rapidly putrefy; but remains dry, and shrinks up. Again, whatever tends to prevent the return of the venous blood from a part (as a firm ligature placed round a limb—or the constriction of the gut in strangulated hernia) is favourable also to the production of mortification. Probably here too the direct or indirect pressure made upon the arteries is chiefly concerned in occasioning the death of the part. We see limbs mortify sometimes after their principal artery has been tied for the cure of aneurism, when the collateral arterial circulation fails sufficiently to re-establish itself: we see the same thing when the passage of the blood through the main artery is stopped by external injuries.

There is also a very curious form of chronic and dry gangrene produced by the continued use of diseased grain as food—and particularly of the spurred rye: and to this, as a distinct disease, I may perhaps have occasion to direct your attention hereafter.

The different stages and events of inflammation that have now been described are accompanied by corresponding disturbances of the system at large. These were touched upon (barely mentioned, however) in that rough and general outline which I attempted to sketch in the outset, of the various phænomena of inflammation; and to which I have since referred as a type. They require, for many reasons, to be considered somewhat more minutely.

When, as *surgeons*, you have to deal with *external* inflammation, you have no difficulty, in the first place, in ascertaining its actual existence: you see it; and you know besides, merely by looking at the part, and

perhaps handling it, what changes it has undergone. You may perceive that the opposite lips of a wound have adhered; or that a phlegmon, in which you can also distinguish fluctuation, has assumed a pyramidal form, and begins to look white upon its summit : or you observe that the abscess has broken, and left an ulcer behind it, which pours out pus, and which shows a tendency to contract, or to enlarge itself : or you may remark the alteration of colour and of temperature which denotes the approach of mortification, or the actual death of the part. The mere exercise of your external senses apprises you, not merely that there is inflammation, but also whether it is of the *adhesive* kind ; or has reached the degree of *suppuration ;* or has produced *gangrene.* At the same time you do not fail to notice the nature of the *constitutional* disturbance that may be present; and the knowledge thus obtained of the local and of the general symptoms determines your plan of treatment.

But when, as *physicians*, we have to do with inflammations of *internal* parts of the body, and when the changes attendant upon that process are concealed from our view, the case is very different. We should often be unable to make out the nature of the disease at all, if the presence of pyrexia did not instruct us. Sometimes the constitutional disturbance is all that is apparent, until after death. And, as the disease proceeds, we frequently are able to judge that this or that *event* of inflammation has taken place, only by observing the indirect symptoms which declare themselves through the medium of the system at large. Yet it is in many cases of the greatsst importance to mark the transition from one stage or event of inflammation to another ; and to learn whether, and in what degree, the more urgent of the symptoms depend upon the inflammation itself; or upon the effects which it has produced. I do not mean to say that we have not, sometimes, as sure indications afforded us by *direct* symptoms, cognizable by the sense of hearing or of touch, of the state of internal organs, as we *could* have if they were exposed to our view. To these direct symptoms I am not now about to refer ; they must be spoken of in connexion with the diseases to which they belong. But the information which the physician gains from what may be called *constitutional* symptoms is *always* highly valuable ; and it is *sometimes* the *only* information that offers any guidance to the remedial measures he ought to adopt.

Inflammatory Fever.—Inflammation, sufficiently extensive or intense to disturb the general system at all, is attended with pyrexia : and the presence of pyrexia, when the part affected is unseen, marks the *nature* of the disease. The most prominent of the symptoms that denote the existence of inflammatory fever are debility and chilliness ; followed by, or alternating with, increased heat of skin ; and increased frequency and force, and often *hardness* of the pulse ; with considerable derangement of most of the natural functions of the body. Commonly there is headache and confusion of thought, languor, thirst, loss of appetite, a furred or white tongue.

Among these leading symptoms, the chilliness, often amounting to shivering, has this particular importance attached to it, that it marks the *date* of the febrile disturbance. And it is worth observing, that rigors more commonly attend the commencement of spontaneous inflammation than of inflammation caused by external injury.

Now, without going more into detail—of this febrile condition belonging to the early stage of inflammation, I make the following remarks.

1. That it generally *succeeds* the manifestation of the local symptoms of the inflammation : and that we cannot, therefore, help considering the fever as the natural *effect* of the inflammation.

Kaltenbrunner describes an experiment of this kind. He says, if a drop of alcohol be applied to the web of a frog's foot, the blood presently flows towards the part irritated, and the circulation in it is accelerated ; *congestion* takes place, and follows its known march.

If the dose of alcohol be augmented, the phænomena of congestion increase considerably, and extend over a larger space : at length points of stagnation appearing in the focus of the affected part announce the establishment of *inflammation.*

If the dose of alcohol be still farther increased, we observe that, on the one hand, the inflammatory points of stagnation become larger and more numerous ; and that, on the other, the circumferential disturbances of the circulation extend themselves, so as at length to implicate the whole of the circulating system : they give rise to a *fever*, which is *added* to the *inflammation.* The circulation in the web of the opposite foot is as much accelerated as in the vessels surrounding the inflamed part in the first foot. If the word congestion had not a local meaning, we might call fever (he says) a general congestion.

Perhaps the fever may be owing to the circulation of altered blood throughout the body. We know that the blood *is* altered in these cases, inasmuch as it is found to contain an unusually large proportion of fibrin ; and as it has acquired the unnatural quality whereby, when withdrawn from the body, and allowed to coagulate, it exhibits the buffy coat.

That the febrile state follows the local inflammation in point of time, is then the

rule : but this rule has frequent exceptions. Erysipelas, and all the febrile exanthemata, afford instances of exception ; the fever sets in before any manifestation at least of the local symptoms. These are indeed diseases of a specific kind : but the same is true some- times of diseases that appear to be simply inflammatory ; such as inflammation of the lungs, and cynanche tonsillaris. There are other cases in which the local symptoms and the general febrile disturbance appear to burst forth simultaneously : this is seen in certain instances of pleurisy, and of peri- tonitis.

2. Again, it is a curious circumstance that the inflammatory fever is not always propor- tioned, in its degree of violence, to either the size or the importance of the part inflamed. The pyrexia is often very strongly marked in that common complaint, the quinsy, inflammatory sore-throat, cynanche tonsillaris—which can scarcely ever be said to imply much danger.

3. The situation, the extent, and the degree, of the local inflammation being the same, the fever commonly runs higher in young, and in plethoric persons, and in those of sanguine temperament, than under the opposite conditions.

4. The inflammatory fever may be modi- fied in the outset, or very early indeed, by the nature of the part upon which the in- flammation has seized. I have several times mentioned the peculiar depressing effect upon the action of the heart produced by inflam- mation of the stomach and bowels, and of some other of the abdominal organs ; and particularly by inflammation involving their peritoneal covering. This lowering influence (which is analogous to that of certain me- chanical injuries to the abdomen) has been supposed to depend upon the subduing and sickening kind of pain which is apt to accompany inflammation of these parts. However it may arise, it gives a peculiar character to the inflammatory fever ; lessens the amount of reaction, or abridges its dura- tion ; affects especially the quality of the pulse ; and carries with it a strong tendency towards death by asthenia.

5. There is no doubt either that the cha- racter of the inflammatory fever is liable to be considerably modified, from the first, by the previous habits of the patient. In per- sons who have been habitually intemperate— or who have been subject to long-continued excitement of the nervous system of any kind—the fever which attends inflammation approaches more or less to the typhoid form, from the very beginning. The febrile reaction is less strongly pronounced. The functions of animal life are sooner and more deeply in- volved in the train of morbid actions. Stupor and delirium are apt to occur ; with extreme debility and irregular movements of the volun-

tary muscles. Still more conspicuous are these peculiarities in some cases of inflamed veins ; and whenever inflammation is pro- duced or accompanied by the introduction into the system of certain animal poisons.

6. The relative duration of the inflamma- tory fever is subject to some variety. It may persist for a little while, for a few days even, after all the local signs of inflammation have disappeared : this happens chiefly in persons of an irritable habit. We watch such cases narrowly, not without some ap- prehension of a relapse. On the other hand, a rapid abatement of the febrile symptoms sometimes takes place, while the local changes continue, or even for a time increase in ex- tent. Nevertheless, we hail this change as a favourable augury of the ultimate result.

Hectic fever.—When inflammation, exter- nal or internal, has gone on to the formation of pus, *that* event is frequently marked by the supervention of peculiar symptoms, and the character of the fever undergoes, for the most part, a striking alteration.

It is very important to ascertain the time when this event of inflammation takes place, or is at hand : for the measures which might have been proper and necessary while any prospect remained of the *resolution* of the inflammation, may be useless, and even hurt- ful, if continued after that prospect is at an end.

When the surgeon perceives any indica- tion of the formation of pus in an external part, he mostly despairs of being able to bring about resolution ; ceases to abstract blood from the part, or from the system ; and ap- plies perhaps warmth and moisture, by means of a linseed poultice, to promote the suppuration. And a corresponding change of plan is required in internal inflammations.

Now the *commencement* of suppuration is often marked by rigors ; and its *continuance* by hectic fever.

If, after the symptoms of inflammation have lasted for a certain time, the patient is attacked by cold shiverings, followed by some increase of heat, that circumstance alone is enough to make us suspect that pus is formed, or is about to be formed : and to teach us that the measures employed to effect a reso- lution of the inflammation have not been successful.

Rigors are very striking symptoms ; but they are by no means necessarily connected with suppuration. They usher in, as I pre- sume you know, most forms of fever, appear- ing at the very outset of the disease. They recur, at regular intervals, in ague. Slight causes will, sometimes, produce them. They often follow the introduction of a bougie into the urethra. But when they occur *after symp- toms of internal inflammation have been for some time present*, they denote, in most cases,

the production of pus in the part or organ inflamed. Sometimes one such shaking fit only is observed : sometimes several take place. When they recur, it is usually at irregular intervals : but cases do happen in which the shiverings indicative of internal suppuration are so strictly periodic, that unless all the circumstances be carefully taken into the account, they may be mistaken for signs of intermittent fever.

The leading symptoms of *hectic fever* (by which, I say, the *continuance* of suppuration is commonly marked) are an abiding frequency of pulse ; alternations of chilliness with heat and flushing, followed by perspiration ; a gradual wasting of the body ; and progressive debility.

I shall hereafter have to describe to you a very different kind of disease, in which, however, there is a succession of symptoms resembling more or less closely the series that characterizes hectic ; I mean *remittent fever :* the succession of symptoms being chilliness, heat, perspiration. But these two disorders are in most cases discriminated from each other by the circumstances under which they occur.

The symptoms of hectic fever often creep on, at the outset, insidiously, and almost imperceptibly. " A very slight degree of emaciation, a pulse a little quicker than ordinary, with a small increase of heat, especially after meals, are often the first symptoms which can lead us to suspect the formation of hectic." Cullen has described hectic fever as consisting of two exacerbations in the 24 hours—one about noon, the other towards evening ; but in many cases the latter alone is distinctly marked. The patient feels shivery and cold towards night ; then the skin becomes hot and dry, especially in the palms of the hands and the soles of the feet, and the pulse *more* frequent ; and in the middle of the night or towards morning, he wakes from short and uneasy sleep, in perspiration, which is often profuse. Sometimes, however, there are two or three fits in a day. The paroxysms are shorter, and less regular, than those of intermittent or of remittent fever. Each of the three phænomena constituting the series may, in its turn, be wanting : and even if the paroxysms are regular for two or three times together, they never continue to be so. Many circumstances connected with the paroxysm itself are very distinctive. " The hectic patient," says Dr. Heberden, who has left us a very good account of this affection in his *Commentaries*, " is very little or not at all relieved by the breaking out of the sweat ; but is often as restless and uneasy after he begins to perspire as he was while he shivered or burned. All the signs of fever are sometimes found the same after the perspiration is over ; and during their

height the chilliness will in some patients return, which is an infallible character of this disorder. Almost all other fevers begin with a sense of cold, but in them it is never known to return and to last twenty minutes or half an hour, while the fever seems at its height, which in hectic will sometimes happen."

Hectic fever is one of the fearful accompaniments, and sometimes the most strongly marked symptom, of pulmonary consumption : and where the existence of that complaint is suspected, yet a matter of doubt, we look for indications of hectic fever with the greatest anxiety.

With relation to hectic fever, considered as an indirect symptom that suppuration has succeeded to inflammation, and is still going on, it will be worth your while to notice the strong contrast it offers in many particulars, to the *inflammatory* fever that attends the earlier stages of inflammation.

The pulse loses much or all of its *hardness* and strength, but it remains permanently more frequent than the pulse of health : the appetite returns in great measure ; the thirst abates ; the tongue, instead of being covered with a white fur, becomes clean and moist, and towards the end is sometimes unnaturally red, or speckled with aphthæ : there is no longer headache or confusion of thought.

A few more touches will suffice to fill up the picture of hectic fever.

The face is usually pale ; but during the exacerbations it is partially flushed, and very often a characteristic circumscribed red spot appears upon either cheek. Besides the evident emaciation, various minor changes mark the want of proper nourishment : the skin, when not perspiring, is harsh and scurfy ; little branny scales may be rubbed from the legs, merely by the friction produced in drawing off the stockings ; the hairs become fine and fall off ; the finger-nails are incurvated into an adunque form ; and the sclerotic coat of the eye, as seen through the conjunctiva, becomes of a pearly white. As the disease advances œdematous swellings of the ankles are very apt to come on.

The connexion between hectic fever and the formation of pus in some part or other of the body is so frequent, that it has been deemed, by persons of great experience and sagacity, a *universal* fact. Dr. Cullen tells us, in his *First Lines*, that he had never seen hectic in any case, when there was not evidently, or when he had not ground to suppose there was, a permanent purulency or ulceration in some external or internal part. And Dr. J. Thomson, speaking of the opinion that hectic might occur independantly of suppuration, uses these words : " But till facts more decisive, and cases more accurately described than any which have yet appeared are produced in proof of that

opinion, I shall think myself justified in adopting the *common* opinion ; and in believing that hectic fever is in every instance connected, if not with the *absorption*, at least with the *formation* of pus.''

The notion alluded to in the latter part of this quotation was at one time very commonly entertained, viz. that hectic fever resulted from the reabsorption of pus into the blood ; but there are many facts decidedly opposed to this belief. Considerable collections of matter not unfrequently disappear, *i. e.* are taken up again into the blood, without occasioning the slightest approach to hectic. Again, hectic will accompany, and be kept up by, a scrofulous joint attended with an open sore, and it will sometimes cease at once, and completely, upon the removal of the diseased limb by amputation ; although a greater quantity of pus is secreted by the stump, than had been secreted in the diseased part previously to the operation. Facts like these prove, I think, that hectic is not simply a consequence of the absorption of pus into the blood : and they seem to have suggested to Mr. Abernethy the notion (which was also held indeed by John Hunter) that sympathetic hectic fever is a *teased* action of the system, endeavouring to throw off what annoys it : the cause of irritation being removed, it ceases forthwith.

And there is another conclusive circumstance to be mentioned. Notwithstanding the opinions I just now quoted from Cullen and Thomson, I believe few persons who have attended to the subject, doubt, now, that there is such a thing as *idiopathic* hectic ; hectic unconnected at least with suppuration any where. We often see hectic, or a general state of the system not to be distinguished from hectic, in mothers who have suckled their infants too long : we see it too, sometimes, if I mistake not, in newly married husbands : and it may be noticed as occurring more or less distinctly in those who labour under diabetes. What is common to all these cases is, that there is an habitual drain upon the system beyond what the nutriment taken into it can supply and counterbalance. It is certain, too, that hectic fever sometimes happens in phthisis, not only before there has been any expectoration of puriform matter, but prior even to the softening and suppuration of a single tubercle. I call to mind one instance in particular of this. The hectic was distinctly marked, and continued long. The patient died, at last, comatose, after two attacks of convulsion. Two or three large scrofulous tumors were found imbedded in the substance of his brain. Various other organs were infested with tubercles ; but the tubercles were all of them still hard and crude.

However, setting aside these rarer cases of exception, there can be no doubt that

hectic fever, considered as a constitutional symptom of mischief that *may* reveal itself by scarcely any other token, and especially as a sign of suppuration, deserves all the attention we can give it ; and for that reason have I spoken of it rather at large. Whenever I mention hectic fever in the farther progress of these lectures, you will know all that I wish to express by that term.

Typhoid fever.—I have very little to say at present respecting that modification of the general febrile disturbance, which sometimes attends *mortification* as an event of inflammation. I stated before that the fever is apt in these cases to assume the typhoid form ; and to be characterized by sinking of the pulse, shrunken features, coldness and clamminess of the skin, a dry and black tongue, low muttering delirium or stupor, tremors of the voluntary muscles, with spasmodic startings of their tendons, and insensibility to the passage of fæces and of urine. I must, however, now inform you that these typhoid symptoms are no constant or necessary concomitants of mortification. The natural mode of death, under gangrene, is death by asthenia. But the typhoid state involves the nervous functions, and tends to death by coma. Whenever, therefore, typhoid symptoms supervene upon inflammation which ends in sphacelus, they may with much probability be attributed to some contamination of the blood by an animal poison ; and such contamination may have taken place previously to the mortification, and have even helped to produce it, as when inflammation arises during the progress of the contagious febrile disorders ; or it may occur as a consequence of the mortification itself, by direct absorption into the system of some of the putrefying and poisonous elements, into which the dead part has been resolved.

One circumstance, worth bearing in mind, as sometimes indicating the supervention of internal mortification, is the sudden cessation of pain : giving hope to the patient and his friends that the danger is over; but not deceiving the experienced physician.

Modification of inflammation by differences of tissue.—So much, then, for the local and constitutional events of inflammation, considered generally.

It remains for me to make some observations upon the modifications of inflammation, according as it affects the different tissues of which the body is composed. Many of these observations I have, indeed, already anticipated ; but it will be useful to bring together, under one view, the most material facts ascertained on this matter.

Cellular tissue.—When inflammation affects the *cellular tissue*, all the events of

inflammation which I have taken some pains to describe are apt to occur; and for that reason, inflammation of this tissue, as it exists beneath the skin, was chosen by me as a convenient type, or general representation, of the inflammatory process. There is the less necessity, therefore, that I should take up much of your time in speaking of the characters of inflammation exhibited in cellular tissue. There is a strong tendency to form circumscribed abscesses : the extension of the suppuration is prevented by a wall of lymph thrown out around it. The adhesive inflammation sets bounds to the suppurative. There is a good deal of pain when the cellular tissue is so situated that tension is occasioned by its swelling.

But sometimes no such boundary wall is erected, and the inflammation spreads and diffuses itself, and becomes a very terrible disease, destroying the cellular tissue over a large and undefined space, by a process between that of sloughing and that of suppuration. When the skin is implicated also in the inflammation, the disease is usually called *erysipelas phlegmonoides*: when the skin is not involved, it is called *diffused inflammation of the cellular membrane*. This diffused form of inflammation frequently follows the introduction of animal poisons into the system; and accompanies the inflammation of veins and of absorbent vessels. It is this disease which is so often fatal to members of our profession, when it results from wounds or punctures received in opening dead bodies. Dr. Craigie has recently put forth the opinion that in these cases of spreading inflammation it is the *adipous* tissue that is affected.

Substance of glands and solid viscera.—The substance of the *larger glands, and of the solid viscera* of the body, suffers changes analogous to those observed in the cellular tissue : probably because cellular tissue enters largely into their composition. Acute inflammation of the liver, when it does not terminate in resolution, leads to abscess in that organ. Abscess is rare in the lungs, perhaps for the reasons mentioned in the last lecture. Gangrene is also very rare in the pulmonary substance : and quite unknown, I believe, in the liver, and in the kidney. Inflammation of the latter organ is not unfrequently attended by purulent collections. Inflammation of the substance of the viscera is not, in general, attended with much pain.

The cellular tissue is liable to be rendered permanently thick and hard by *chronic* inflammation, as well in the parenchyma of internal organs as where it is spread out beneath the skin, or beneath serous or mucous membranes. Chronic induration and thickening of the cellular tissue which composes Glisson's capsule is no uncommon result of slow inflammation; producing that particular change in the liver which the French pathologists denominate *cirrhose;* but of which the essence is atrophy of its lobules from compression of its nutrient arteries.

Serous membranes.—The inflammation of *serous membranes* is characterized by sharp and severe pain; and by hardness of the pulse; and by buffy blood; by its tendency to spread; by the effusion of serous fluid, and of coagulable lymph; and sometimes, when the inflammation is very violent, or air gets admitted to the inflamed surface, by the effusion of pus. Speaking generally, however, it is *adhesive inflammation* which we expect in inflammation of this tissue. False membranes, consisting of organized lymph, belong to it : and the agglutination of contiguous surfaces. Sometimes the lymph, instead of being deposited in flakes or layers, appears in the form of numerous small granules : this is a phenomenon frequently observable in inflammation of the arachnoid, and of the peritoneum. Sometimes it has a villous or papillary or shaggy arrangement; or is cellular like a honey comb. This is common in the pericardium. The surface (to use the happy simile of Laennec) resembles that which may be produced by separating two flat plates between which a layer of soft butter had been spread : and it probably depends upon a similar cause; since in health a perpetual sliding motion of the pericardium over the heart is going on. Ulceration of a serous membrane is very uncommon. I mean ulceration *commencing* in that tissue : for these membranes are frequently perforated by ulcers which approach them on their attached side, and which begin in other tissues, especially the mucous. Neither does mortification occur in serous membranes, except sometimes by communication from other parts. The effect of *chronic* inflammation of the serous surfaces is to thicken, harden, and pucker them. We see this effect in the omentum frequently; in the peritoneal covering of the liver; in the serous membrane which forms so large a portion of the valves of the heart.

Synovial membranes.—The *synovial membranes* have a strong analogy to the serous. Gendrin includes the two in the same category : yet their behaviour under inflammation offers, in some respects, a marked distinction between them. They are less *liable* to inflammation than the serous membranes : they rarely throw out coagulable lymph, and, consequently, adhesion of their opposite surfaces is very uncommon. Joints do not become immoveable, or what is called anchylosed, in consequence of the agglutination of their synovial surfaces; but, generally, by means of granulations forming upon those surfaces after they have ulcerated. Very seldom indeed does pus form in the synovial sacs, except (again) the inflammation has been caused by mechanical injury, which has laid open the joint, and admitted air.

When this is the case, very serious constitutional disturbance is apt to take place, and the existence of the sufferer is endangered. That this does not depend upon the *mere violence of the exciting cause* is evident from the circumstance that the same acute inflammation, the same general affection of the system, and equal danger, often result from the careful incision made into a joint by the surgeon, for the purpose of removing loose portions of cartilage. I have now at the hospital an out-patient who has, among other ills, a large cartilage floating about in fluid in one of his knee-joints : but I believe that Mr. Arnott, whom I have consulted on the case, will be very slow to recommend its removal, until the inconvenience produced by it is so great as to incapacitate the patient from pursuing his employment, and until other methods of relief have failed. Suppuration of the joints is also one of the occasional consequences of phlebitis. Inflammation of the synovial membrane speedily leads to a *serous effusion* into the joint : which often, especially in rheumatism, is as speedily taken up again.

Tegumentary membranes.—Let us next inquire into the modifications which inflammation undergoes when it affects the tegumentary membranes.

Skin.—Considering the *skin* as *one membrane*, and neglecting its subdivisions into epidermis, rete mucosum, and cutis vera, we find that inflammation assumes a variety of forms in this external covering of the body. Many of these belong to specific diseases, and do not fall within my present purpose, which is that of noting how *common* inflammation varies in the different tissues.

When the inflammation is superficial, it frequently is denoted only by a diffused red blush, which may be banished for a moment by the pressure of the finger, and which after a certain time disappears of its own accord — terminates by resolution ; the only consequence of the inflammation being the separation of the cuticle in small branny fragments ; in one word, *desquamation*. We call the superficial inflammation, in this case, *erythema*. If the inflammation has been a little more intense—as in some cases of *erysipelas*, in *scalds*, and in that which we are every day exciting by *cantharides*— a serous fluid is poured out, which elevates the cuticle in larger or smaller patches of vesication. Remove the cuticle and admit the air, and the *serous* effusion becomes *purulent* effusion : and if the inflammation be pressed beyond a certain point by any *other* stimulus besides that of air, we may have pus poured out. Erysipelatous (which is also a specific) inflammation of the skin, is characterized by its remarkable tendency to spread : and a most singular circumstance attends several of the other specific inflammations of the skin—viz. that having occurred

once, they never occur again : this peculiarity belongs, however, to the great constitutional diseases, of which the skin affection forms merely a part.

Mucous membranes. — Inflammations of the *internal* tegumentary membranes —of the three internal surfaces that communicate with the air, and are clothed with mucous membrane —are very interesting to the physician : and the first thing which strikes our attention in respect to them is the indisposition they manifest to adhesive inflammation : and we are struck at the same time with the *beauty* of this provision. If the mucous membranes were as ready to throw out coagulable lymph, and to adhere to each other, as the serous, almost every occurrence of inflammation in them would prove necessarily fatal ; by closing up the *inlets* of the air-passages ; or the *outlets* of the urinary passages ; or any part of that long mucous canal which, passing through the body, requires a free opening at both of its extremities. But the inflamed mucous membrane pours out serous fluid ; or viscid mucus ; or pus ; or blood. Inflammation of these membranes is, however, sometimes attended with the exudation of something which is very like coagulable lymph, and which has been considered (but, in my opinion, erroneously considered) to be such lymph. The tracheal, bronchial, and pulmonary mucous membrane, the œsophageal, the intestinal, and that which lines the uterus, are all more or less subject to the formation of adventitious membranes under inflammation. Casts of the smaller branches of the air tubes have, in rare instances, been repeatedly coughed up in large quantity ; constituting what have very inaptly been called *bronchial polypi*. The membranous exudation of croup is well known : a tubular substance is formed in the trachea, and, sometimes, fortunately expelled : but too often it suffocates the patient. Similar concrete exudations, sometimes in irregular shreds, are occasionally voided by stool. It is said that a long membranous mass of the same kind, and resembling in size and shape an earthworm, has been expelled from the urethra ; having formed there in consequence of the injudicious use of stimulating substances, injected with the view of checking the more innocent effusion of pus. The films, or membrane-like flakes which are thus incidental to inflammation of the mucous surfaces, resemble I say in their general appearance and disposition the strata or layers of coagulable lymph which are the ordinary product of inflammation of the closed serous surfaces. But they differ from these in some remarkable points. They are softer. They never contract permanent or strong adhesions to the subjacent inflamed membrane ; but are partially separated from it by the intervention of thinner matters, serous or puriform.

Above all, they never become organized. They appear to consist of inspissated and altered mucus; and are composed, in a great measure, of albumen. An opinion has been entertained that the *want of apposition* of the opposite surfaces has a great deal to do with their indisposition to cohere. The mucous *air* tubes are kept open and apart by their *structure :* the stomach and intestines by their *contents*, or by the frequent passage of solids or fluids through them : and, therefore, (it has been supposed) they have no *opportunity* of adhering. But there can be no doubt that these mucous membranes are but little disposed to throw out true lymph at all : and when their opposite surfaces do grow together, I believe it will almost always be found that some abrasion or ulceration of the mucous surface has previously happened.

Inflammation affecting the mucous membranes has sometimes a strong tendency to spread and wander : sometimes, on the contrary, it is strictly confined to a small and definite space. In the former case it commonly restricts itself for a long time, or altogether, to the mucous tissue, leaving the neighbouring tissues untouched. In the latter it is apt to penetrate to the subjacent parts, and to produce obvious and enduring alterations of structure. The membrane becomes fastened to the parts which it clothes, and not unfrequently it ulcerates or sloughs.

The spreading form of inflammation is most often met with in the air-passages. Ulceration and sloughing, and circumscribed inflammation, are more common in the alimentary canal.

There is a remarkable contrast between the serous membranes and the mucous, in respect to the *pain* which attends their inflammation. Very little pain is experienced in many cases when inflammation affects the mucous lining in any of the three systems, except towards their openings, where the membranes are about becoming continuous with the external skin : in the mouth and throat, for example, the pharynx, the rectum, the vagina, the extremity of the urethra. And as inflammation of the mucous membranes is attended by less *pain*, so also it is accompanied by less *fever* than when the serous membranes are attacked ; and the blood more seldom exhibits the buffy coat.

Muscular tissue.—The *muscular tissue* appears to take on the actions of inflammation very reluctantly : and its vessels seldom, if ever, pour forth any of the products of inflammation. The chief effect of inflammation upon muscle is the destruction of its contractible properties. Serum and lymph, and even pus, are sometimes found diffused through muscular parts ; but there is reason to believe that these effusions are rather the consequence of inflammation of the cellular tissue which enters into the composition of the muscle, which ties together its muscular fibres, than of inflammation of those fibres themselves.

Arteries.—I have remarked already that inflammation of an *artery* presently leads to the effusion of lymph, and the coagulation of the blood, in the artery. But arteries do not readily inflame, except under mechanical injury : they do not often suppurate either : and they possess a singular power of resisting mortification. Dr. J. Thomson declares that he has seen cases of phlegmonous erysipelas, in which " several inches of the femoral artery were laid completely bare by the gangrene, ulceration, and sphacelus of the parts covering it, without its giving way before death."

Veins.—Inflammation of the *veins* is much more common than that of the arteries : and it is a disease of fearful interest. In some cases it leads to a deposit of fibrin upon the inside of the vessel, " furring it over," as Mr. Hunter says. The blood soon coagulates, and blocks up the inflamed vein, or leaves, perhaps, a narrow passage in its centre. From this mechanical obstruction to the current of the blood new symptoms arise. The part from which the venous trunk receives its tributary branches becomes œdematous or dropsical. Inflammation of the femoral vein, obliterating its cavity, is the essence of the complaint known to pathologists under the name of *phlegmasia dolens :* a complaint which may happen to persons of any age, and of either sex : but which is most common in women soon after parturition.

This, which may be considered the adhesive form of phlebitis, is also its most innocent form. Too frequently the inflammation runs into suppuration ; and then it proves a most terrible and almost hopeless disorder. The vein remains pervious ; pus, of an unwholesome and poisonous quality — or some morbid product of the inflammation — is carried into the blood; which thus scatters, in its course, the seeds of inflammation, and determines the rapid formation of purulent collections, in various and distant parts of the body, and especially in the lungs, the liver, and the larger joints. Great constitutional disturbance ensues, and fever of a typhoid type is established. To this, the destructive form of the disease, parturient women are also peculiarly liable. Phlebitis of the uterine veins constitutes the source of the most dangerous and deadly varieties of puerperal fever. It is the same disease which gives to a vast majority of those surgical operations that are followed by death, their fatal character.

Substance of the brain.—We hear continually of inflammation of the *brain;* but

what is so called is, most commonly, inflam-
mation of the *membranes* which invest the
brain. Inflammation of the cerebral sub-
stance itself is, however, not very uncommon ;
but it is more frequently the result of injury
than of spontaneous disease, and it is usually
confined to a limited portion of the brain.
Softening and suppuration are its ordinary
events.   Sometimes pus is met with oc-
cupying a distinctly circumscribed space ;
the pus is collected into an abscess.   Some-
times, on the other hand, it lies loose, as
it were, and surrounded by broken-down
cerebral matter, or it is infiltrated into the
cerebral pulp.   Around the softened portions
the inflamed substance of the brain is more
dense and firm, sometimes, than is natural.
Whether its being so owing to the presence of
coagulable lymph, has not (so far as I know)
been clearly ascertained.   Mortification must
be very rare in the nervous substance.   Dr.
Baillie has described it as occurring after
violent injury.   Once or twice in my life,
portions of brain have been shown to me,
protruding through an aperture in the skull,
dead, of a dark colour, and having an offen-
sive smell.   Excepting in these cases of
hernia cerebri, I have never seen sphacelus
of the brain from any cause.

Perhaps, however, I am incorrect in saying
this.   I formerly told you that portions of
the brain often become soft and diffluent,
when there has been no inflammation ; but
simply from atrophy, depending on a
diseased state of the nutrient arteries of the
brain.   Now some persons call *this* morti-
fication of the cerebral substance.   They
consider it quite analogous to the gangrena
senilis, which results from a similar cause,
although it happens in another part of the
body.   The *nature* of the change, they say,
is the same, although *the physical characters
of it* differ.   If this be so, I have seen gan-
grene of the brain some scores of times : but
still I should be able to declare, that with,
perhaps, the exception already mentioned,
I have never seen unequivocal mortification
of the cerebral substance as the result of
inflammation ; which is what we have now
been considering.

This concludes, gentlemen, what I have
to say concerning the phænomena of com-
mon inflammation, as they are perpetually
witnessed in the various textures of the body.
I have not, indeed, gone through all the
tissues ; I have said nothing of the peculiar
effects of inflammation, in cartilages for
example, and in bones ; but I have glanced
at all those tissues in the inflammation of
which the physician is chiefly concerned ;
upon such points as I have purposely
omitted, you will be amply instructed by my
colleague, the professor of surgery.

ON THE
RESULTS OF AMPUTATIONS.

To the Editor of the Medical Gazette.

Sir,

The accompanying paper was prepared
for the Glasgow Medical Society nearly
two years ago.   I had laid it aside, but
at the recommendation of the president
of the section, read it before the medi-
cal section of the British Association,
at their meeting here in September.
Perhaps you may find a place for it in
your journal.—I am, sir,

<div style="text-align:right">
Very obediently yours,
J. A. Lawrie, M.D.
</div>

Professor of Surgery Anderson's University,
Surgeon Glasgow Royal Infirmary, Glas-
gow Lock Hospital, &c.

Glasgow, Oct. 29th, 1840.

The frequency of its performance, the
mutilation which it causes, its severity,
and its immediate and ultimate dangers,
combine in making the operation of
amputation one of the most important
subjects which can occupy the atten-
tion of the practical and operative sur-
geon : it is peculiarly so to the hospital
surgeon in such a city as Glasgow.   In
private practice, in the better ranks of
society, it is an operation of compara-
tively rare performance ; whereas in
hospitals it exceeds many fold all the
other capital operations combined.
In this city and neighbourhood, the
character of the climate strongly pre-
disposing to diseases of the joints ; the
number of our public works ; the extent
and variety of machinery employed in
our manufactories ; the amount of our
shipping, and number of steam vessels ;
our coal mines and stone quarries ; the
great increase of building, and the
certainty that ere long Glasgow will be
the centre from which numerous rail-
ways will radiate, give to the operation
of amputation, by greatly increasing
its frequency, an interest exceeding
perhaps all others performed in our
infirmary.

I need not inform the members of
this section that this subject has at-
tracted much attention, and that of late
years many parts of it have been so
much improved as to leave little farther
to be desired.   The subject of this
essay, "The Results of Amputations,"
has not, however, met with that con-
sideration to which its importance ap-
pears to entitle it.   Although success

may not in every instance be a fair test of the propriety of treatment adopted in individual cases; in the aggregate, it is the best—indeed, the only true—criterion by which to judge of operative surgery. For many years the operation of lithotomy, and the removal of cancerous disease, have been tested in this manner, and the result has been that the confidence of the profession has increased in the one, while the other, except as a palliative, has been almost entirely abandoned. I am surprised that the same severity of investigation has not been applied to amputations. Mr. Samuel Cooper, in the last edition of his Dictionary, while he devotes several columns of his closely printed pages to the history of amputations, says scarcely a word of their results. Our best and most recent works on operative surgery are open to the same objection; for while the different methods which ingenuity has suggested for the removal of particular parts are minutely detailed, hardly one word is of the results of their operations, either in the aggregate, or as contrasted with each other. Our military surgeons for many years have been more attentive to this subject than their brethren in civil practice; but until the end of the peninsular war their opinions were by no means in accordance regarding it. Belguer, Surgeon-General to the Prussian army, in a treatise published in 1762, condemns amputation as an operation hardly justifiable under any circumstances. He carried his opposition so far, that "he suffered no amputation to be performed in the Prussian army." He states his success as follows:—" I had at one time during the war, in a military hospital, 6618 wounded patients; of them 5557 were perfectly cured, 195 were able to do duty in person or to work at any trade, 213 remained incapable of any labour, civil

or military, and 663 died. The 195 and 213 invalids were of the number of those who had their bones broken and shattered, or, in other words, whose wounds were complicated and dangerous. Of the 663 who died, 408 only died from shattered bones, which number, 408, is equal to that of those who were cured without amputation, although their wounds had been of the same kind." One half therefore of his severe wounds of the extremities died, the other lived without operation. "If," continues Belguer, "after making these calculations, we compare them with the prodigious number of married men who, at the beginning of the war, had their limbs taken off on account of dangerous wounds, of whom scarcely one or two escaped with their lives, we may safely conclude that much the greater part of these 408 men cured and sent to the invalids, would have died if amputation had been performed."

The result of Belguer's experience would thus seem to be, that of 6618 wounded, 916 were cases requiring amputation, of whom 408 died, 213 were incapable of any labour, and 195 were able to work at any trade.

These opinions do not seem to have influenced the practice of British military surgeons, who never seem to have doubted the propriety of amputations in certain severe accidents. With them the preference to be given to primary or secondary amputations after gunshot injuries, formed the principal ground for difference of opinion. Wiseman and Manby were in favour of immediate amputation, while John Hunter was an advocate for the secondary. Towards the close of the peninsular war, British military surgeons were almost unanimously in favour of the former. Mr. Guthrie, in his work on Gun-shot Wounds and Amputations, gives the following tables:—

I. *Amputations performed at hospital stations.—Secondary.*

	No. of Amputations.	Died.	Discharged Cured.	Under Treatment.
Amputations of upper extremity . .	296	116	105	75
Amputations of lower extremity . .	255	149	65	41
Total	551	265	170	116

II. *Operations performed on the field of battle.—Primary.*

	Number of Cases.	Died.	Discharged Cured.	Under Treatment.
Amputations of upper extremity . .	163	5	64	94
Amputations of lower extremity . .	128	19	43	66
Total	291	24	107	160

From these tables it appears, that of 551 cases of secondary amputations, 265, or nearly one half, died. Of 291 cases of primary amputations, 24, or nearly one in twelve, died. Farther, the comparative loss in secondary or delayed operations, and primary or immediate, is—

	Secondary.		Primary.
Upper extremities .	12	to	1
Lower extremities . .	3	to	1

These tables appear quite conclusive as to the propriety of primary amputation in military practice. In other respects, however, they are not so satisfactory as could be wished. The cases marked " under treatment," in both tables, having passed the periods of danger, are considered as recovered. In civil hospital practice, I would not consider a patient recovered until he had left the hospital ; and as the cases under treatment amount to 276, they cannot be looked upon as accurate data for estimating the results of amputations.

In the MEDICAL GAZETTE for June 1838, there is a paper by Mr. Phillips, entitled " Observations arising out of the Results of Amputations in different Countries." He says (p. 459), the amputations included in this inquiry are those of the arm and forearm, leg and thigh. The whole of them have been performed in the last four years in civil hospitals, and in the private practice of hospital surgeons. The details are—

	Cases.	Deaths.	Per Cent.
France	203	47	$23\frac{31}{203}$
Germany . . .	109	26	$23\frac{93}{109}$
America . . .	95	24	$25\frac{5}{19}$
Great Britain .	233	53	$22\frac{174}{233}$
Total	640	150	$23\,7$

By these returns it appears, that the average number of deaths is nearly $23\frac{1}{2}$ per cent. The remainder of Mr. Phillips's paper is devoted to the question of immediate or secondary union of

stumps after amputation for disease, the result of which is, that "attendant on the practice of immediate union is a mortality amounting to 25 per cent.

It must be obvious that the experience of any one of even our best employed surgeons must be inadequate to determine a question of such extent as the results of amputations. Experience on a large scale, and extended over a considerable period, can alone be relied on. It occurred to me, that the records of an infirmary, carefully examined, might in a great measure supply the deficiency, and that details more minute than any I have yet met with might be of use to our hospital surgeons. Assisted by my young friends Dr. M'Lean and Mr. Parish, I have carefully examined all our Infirmary surgical records which I could procure, from the commencement of the hospital to the beginning of 1839, and I have now the pleasure to lay the results before this section. They are neither so extensive, nor, in many instances, so minute as I could wish. Many of the journals have been lost, and others are very carelessly kept; some, on the other hand, are so admirably accurate, that had all the surgical and medical records of any infirmary, from the year 1795 to the present day, been as carefully kept, they would have presented a mass of information capable of determining almost any point in the professional statistics of hospital practice. We are not yet too late, and I would take the liberty of impressing on the members of this section, connected with hospitals, the great value of accurate records. The present state and history of every case ought to be entered in a journal kept for the purpose, and belonging to the hospital, which ought to be premised by a statement of the patient's name, age, constitution, occupation, and residence. (This last is of importance, as enabling us to trace our patients after they leave the hospital,

ud to ascertain the ultimate result of ur treatment.) The date of each ope-ation should be accurately noted, and he true results candidly given. It vould also be a convenience if the in-ices were properly filled up with a olumn for "operations."

The abstract from which these re-narks and tables are drawn consists of 276 cases of amputation of the shoul-ler, arm, and forearm, hip, thigh, leg .nd foot, as they occur in the ournals, from 1794 to the end of 1838.

Of these 276 there were—

    Cured . . 176 . 63·7 per cent.
    Died . . 100 . 36·3 ,, ,,
    Deaths to recoveries as 1 to 2·75

a mortality, I fear, greater than those are prepared for, who have not been n the habit of turning their attention to this subject.

Of the 276 there were—

		Cured.	Died.	Deaths to Recoveries.
Males	216	130	86	1 to 1·6
Females	60	46	14	1 to 3·3

By which it appears that the males are to the females as $3\frac{1}{2}$ to 1, and that he proportionate mortality among the nales is to that among the females as 1·6 to 3·3. The greater mortality among the males is in part, but not altogether, accounted for by the greater number of primary amputations among hem, as will appear in the sequel.

Of 133 cases in which "the number of days in hospital after amputation," is noted, 79 were cured, 54 died. Of the cured, the average number of days under treatment after operation is 42, the least being 8, the greatest 128. Of the deaths, the average is 13 days, the least three hours, the greatest 199 days.

I have divided the cases of amputa-tion into two general classes : 1. Am-tation for disease; 2. Amputations for injuries. The second I have sub-divided into primary and secondary. By primary amputations, I mean am-putations for injuries performed as soon after the accident as circumstances will permit — almost always within the first 24 hours, and without any attempt made to save the limb. By secondary, those cases in which at-tempts have been made, and failed, to preserve the limb, and amputation been performed in consequence of the failure. Each of them I have subdivided into amputations at the shoulder, arm, and forearm, hip, thigh, and leg.

I. *Amputations for disease.* — Of the 276 cases, 153 (more than one half) were for disease.

    Cured   118   77·1 per cent.
    Died   35   22·9 ,, ,,

The following table shews the de-tailed results:—

	No. of each.	Cured.	Died.	Deaths to Recoveries as
Shoulder . . . . ' . .	2	1	1	1 to 1
Arm	17	14	3	$1\frac{1}{2}$ to 7
Forearm	4	4	0	No death.
Thigh	92	73	19	1 to $3\frac{1}{2}$ nearly
Leg	35	23	12	1 to 2 fully
Foot (partial)	3	3	0	No death.
Total	153	118	35	

The diseases with their results were as follows:—

		Males		Females.		Total Cured.	Total Died.	Deaths to Re-coveries.
		Cured.	Died.	Cured.	Died.			
Diseased joints .	98	60	11	23	4	83	15	1 to $6\frac{1}{3}$
Necrosis . . .	12	7	1	2	2	9	3	1 to 3
Caries . . .	21	13	4	3	1	16	5	1 to $3\frac{1}{3}$
Tumors . . .	12	6	2	3	1	9	3	1 to 3
Gangrene . .	5	1	1	2	1	3	2	2 to 3
Ulcers . . .	5	1	4	0	0	1	4	4 to 1

Of which there were—

In this table of the more common amputations, that below the knee is the least favourable. This may be owing to the unfavourable situation at which the operation is performed. In a great majority of instances, even for disease of the foot and ankle, amputation of the leg is performed below the knee, to enable the patient to rest on the bent knee, in using the common "wooden pin." But by a very simple, and by no means expensive apparatus, the patient can walk on the "wooden pin" with his knee straight, and a long stump, instead of being an inconvenience, is a great advantage. The above tables, by pointing out the danger of the common method of operating, should induce us never to remove more of the limb than will insure that the parts which form the stump are sound, and in all cases, except those of necessity, to abandon the operation "below the knee."

It struck me as remarkable, that of the first 30 amputations in the list "for disease," viz. from the year 1794 to 1810 inclusive, 29 recovered, and one died; whereas, of the last 30, 22 recovered, and 8 died. Thinking this might be accidental, I took the central numbers (from 142 to 209, inclusive), and the proportion was 19 cures, and 11 deaths. It is not altogether easy to account for this very remarkable discrepancy. It is obviously by no means complimentary to our modern improvements in operating and dressing. Of the first thirty, in which the cures are, to the deaths, as 29 to 1, it is probable that all the operations were performed by the double circular method, that all the stumps were dressed before the patient left the table, that the dressings were removed by rule, with little regard to the appearance of the stump, and that in all the tourniquet was used. Of the last 30, of which 22 recovered, and 8 died, 28 were single or double flap operations, of which 21 recovered, and 7 died; 2 were double circular, of which one was cured and one died.

Of the supposed recent improvements, there is one which I may be excused for noticing in this place,—I mean delayed dressing. This, after what I thought a fair trial, I have almost entirely abandoned. Its advocates support it mainly on the plea of avoid-

ing secondary hæmorrhage. In my own practice I do not recollect ever to have taken down a stump for this cause, and I believe a little care in tying bleeding vessels on the operating table would prevent it. My objection to the plan of not dressing the stump till six or eight hours after the operation, is the additional suffering that it causes our patients. I have uniformly found my patients complain fully more, and suffer nearly as great a shock, from the delayed dressing, as from the operation itself. As for preventing hæmorrhage, the support of the dressings frequently has this effect; and as for the pain of removing the dressings in the few cases in which hæmorrhage does occur, I believe it to be small in amount in comparison with that which must be occasioned in every case by not dressing on the table.

It is probable, that previously to the publication of Sir B. Brodie's work on Diseases of the Joints, diseased articulations, especially of the knee, classified under the comprehensive appellation "white swelling," were reckoned incurable, and removed at a much earlier period than they now are. Of this I am convinced from a perusal of the cases, as recorded in the journals of the Infirmary. Amputation seems to have been performed for disease, the very proposal of removing which by operation a modern consultation would scout. To prove this I constructed the two following tables. 1 took the 71 first cases of diseased joints as they occur in the journals, from 1794, downwards, and 82 in the journals since 1833, without selection. The numbers 71 and 82 are accidental. (See next page.)

From these tables it appears that, of 71 cases of diseased joints in the early days of the hospital, 30, or 1 in 2·36, suffered amputations; while of 82 in the later period, 22, or 1 in 3·73, only were operated on. The difference is still more striking if we take the knee joint. Of 44, in the early period, 19, or 1 in 2·30, were amputated; while, at the later period, of 57, 11, or 1 in 5·1, were removed, and 1 believe the differences are daily increasing. Of the whole number amputated in the early period, 1 in 9 died; in the later, 1 in 3⅔. Cured, including amputations, in the early period, 40, or 1 in 1¾: in the later 48, or 1 in 1½ very nearly. Cured with-

Tables shewing the results of diseased joints, treated in the earlier and later periods of the hospitals.

		Amputated.		Not amputated.			No of Cases.

out amputation, in the early period, 13, or 1 in 5·4; later period, 31, or 1 in 2·6 From which it appears, that the *number* of *cures* in the two periods is nearly precisely the same, but that in the early period it is effected principally by the amputating knife, in the later by treatment.

Another practical conclusion appears to be, that in disease requiring amputation, after the acute stage has passed, the earlier the amputation is performed the better is the chance of recovery. This is a conclusion at which I have long since arrived, and I would lay it down as an axiom, that the shorter the duration of the disease, and the less the system has suffered under it, the greater is the chance of recovery after amputation, and *vice versâ*. The difficulty is to determine, in the early stage, what disease is curable without amputation, and what must ultimately be removed; a correct diagnosis here, as in almost every other instance, being essential to success.   The error we at present commit is delaying amputation after every rational hope of cure has fled, merely because the patient is not obviously dying.   The consequence has been the reduction of the success of amputations from 1 in 30 to 1 in less than three by one calculation, and from 1 in 9 to 1 in 3½ by another.   To this point I would beg to call the attention

of hospital surgeons in this section. Our predecessors amputated to remove what they reckoned an incurable disease, while the health was still good— we seldom operate except to save life, or rather to preserve from immediate death. Now I feel satisfied, that the number of lives rapidly ebbing from whatever cause, which amputation will save, is very small; and if we restrict our amputations to such cases, we must necessarily be very unsuccessful.   I am no advocate for uncalled-for operation; but surely it is better to save life by removing a disease which we cannot cure, than to delay until treatment and amputation are nearly alike unavailing. A medium between the early and the modern practice of our hospitals would preserve limbs and save lives.   It is, however, but justice to ourselves to state, that the more dissipated habits and lowered condition of our patients, added to the increased size of our hospital, and the crowded state of its wards, must have considerable influence in diminishing the success of our operations.

Primary amputations.—Of the 276 cases, 77, or 1 in 3·5, are primary. Of these 38 were cured, 39 died, the recoveries and deaths being very nearly equal.

The following table shews the results in each limb:—

	No. of each.	Cured.	Died.	Deaths to Recoveries as
Shoulder joint . . .	3	1	2	2 to 1
Arm	23	12	11	11 to 12
Forearm	15	15	0	No death.
Hip	1	1	0	No death.
Thigh*	11	0	11	No death.
Leg	22	7	15	2 to I fully
Foot (partial) . . .	2	2	0	No death.
Total	77	38	39	

The remarkable circumstance in these results is the great mortality. As it stands the deaths exceed the recoveries; and if we exclude the forearm, all of which recovered, the disproportion becomes very great. When we compare this table with that of Mr. Guthrie, the discrepancy is extraordinary. In his primary operations the deaths are to the recoveries as 1 to 12; in ours they rather exceed the recoveries. I believe that in military practice, especially on the field of battle, very many limbs were removed which, in civil practice, we should have attempted to preserve. In our hospital we rarely, if ever, amputate, unless it be obvious that the limb cannot possibly be saved. It is farther probable, that when the patient is seen almost immediately after being wounded, and the amputation is performed on the field of battle, he is in a much better state to bear the operation, and more favourably circumstanced for recovery, than in civil practice, where he is not seen by the hospital surgeon for many hours after the accident, and after being carried, it may be, several miles. Our accidents demanding amputation are rarely uncomplicated : a fall from a height, or the descent of a mass of earth, not only smashes a limb, but injures another limb, the head or other important organ, and inflicts a severe shock on the general system. From these causes the majority of our patients are in such a state of extreme exhaustion and shock when admitted, as to be unable to bear the operation ; and when they rally the reaction is too often typhoid, or attacks a vital organ. Our machinery and railway accidents, which form a considerable

proportion of our primary amputations, are also very frequently complicated, and of themselves severely implicates the constitution. To these must be added the risks our patients run after the immediate effects of the amputation are past, as explained in the sequel. Whether these considerations satisfactorily account for our great mortality it is not easy to determine.

Mr. Guthrie, in his work so frequently alluded to, insists much on the impropriety of operating while the constitution is much under the influence of shock. In this I fully concur, and I would lay it down as an axiom in primary amputations, that the less there is of shock, or in other words, the nearer the patient is to a state of health, the better will he bear the operation, and the more certain will be his recovery ; and I believe it is of the effects of fearful depression that so many of our patients perish.

The second striking peculiarity in our tables is the fatality of our primary amputations of the thigh. In eleven cases there is not one recovery. This was so unexpected, that, fearful of mistake, I re-examined a great proportion of our journals, and could only find one case omitted—a boy, 12 years of age, who was cured. The table ought, therefore, to stand thus : —

	Cured.	Died.	Deaths to Recoveries.
12	1	11	11 to 1

Secondary amputations.— Of the 276 cases, 46, or 1 in 6, were secondary. Of these there were—

Cured.	Died.	Deaths to Recoveries as
20	26	5 to 4 fully.

The following table shews the detailed results :—

	No. of each.	Cured.	Died.	Deaths to Recoveries.
Shoulder-joint . . .	1	1	0	No death.
Arm	13	6	7	7 to 6.
Forearm	3	3	0	No death.
Thigh	24	8	16	2 to 1.
Leg	5	2	3	3 to 2.
Total	46	20	26	5 to 4 fully.

This table *apparently* confirms the experience of our army surgeons, inasmuch as the *aggregate* result of secondary amputation is even more unfavourable than of primary. It however illustrates well the necessity of analysing tables, because so far from proving that secondary are less favourable than primary amputations, it shews the contrary to be true. In order that inferences drawn from tables of this kind be accurate, the amputations performed *on each limb* must be compared, otherwise they are almost certain to be erroneous. The following table illustrates this :—

Comparison of the results of primary and secondary amputations of each limb.

	Primary Deaths to Recoveries.	Secondary Deaths to Recoveries.
Shoulder-joint . . .	2 to 1	No death.
Arm	11 to 12	7 to 6
Forearm	No death.	No death.
Thigh	11 to 1	2 to 1
Leg	2 to 1 fully.	3 to 2

This table shews that in the thigh secondary amputations are much more favourable than primary, in the leg decidedly so, in the forearm equal, in the shoulder superior, and in the arm slightly inferior. The numbers in some instances are small, and require confirmation. The *apparently* more favourable results of primary and secondary amputations in the *aggregate* depends on the greater number of amputations of the forearm (15 primary, 3 secondary), and on two partial amputations of the foot in the former, and none in the latter. It is remarkable that of 22 amputations of the forearm recorded in these tables, there is no death. It would be premature to draw from these tables any conclusion for or against primary as compared with secondary amputations. This much I may say, that the encouragement which they hold out for primary amputations in our Infirmary is not great. The subject requires farther illustrations, and I hope will not be lost sight of. To illustrate it still farther, I have noted the results of 40 compound fractures and dislocations, in which attempts were made to save the limb, and on which no secondary amputation was performed.

Table showing the results of Compound Fractures and Dislocations (not amputated).

	No. of each.	Cured.	Died.	Deaths to Recoveries.
Thigh	5	1	4	4 to 1
Leg	21	15	6	2 ,, 5
Foot and Ankle . .	5	2	3	3 ,, 2
Arm	5	3	2	3 ,, 2
Elbow	2	1	1	1 ,, 1
Forearm	2	1	1	1 ,, 1
Total	40	23	17	

From this table it appears that in attempts to cure compound fractures and dislocations the cures considerably exceed the deaths. The last table (p. 401) shews that when the attempt fails secondary is more favourable than primary amputation. The combined results seem to warrant attempts to save severe cases, in preference to immediate amputation.

Table shewing the number of Amputations performed at different Ages, with the Cures and Deaths distinguished according to sex, and divided into Amputations for Disease—Primary, Secondary.

Ages from	MALES.						FEMALES.					
	Disease.		Primary.		Secondary.		Disease.		Primary.		Secondary.	
	Cured.	Died.	Cured.	Died.	Cured.	Died.	Cured.	Died.	Cured.	Died.	Cured.	Died.
1 to 10	9	4	0	0	1	0	2	0	1	0	0	0
10 20	30	2	5	8	3	7	13	3	2	0	2	0
20 30	17	9	10	14	5	0	6	1	2	2	2	0
30 40	15	6	10	4	2	6	7	2	0	0	1	0
40 50	6	4	4	4	1	6	4	1	0	0	0	0
50 60	3	1	1	5	2	3	0	0	0	0	0	2
60 70	1	3	1	0	0	1	2	0	0	0	0	0
70 80	0	0	2	0	0	0	0	0	0	0	0	0
80 90	0	0	0	1	0	0	0	0	0	0	0	0
	81	29	33	36	14	23	34	7	5	2	5	2
	110		69		37		41		7		7	
Totals.	216						55					
	271											

This table contains only 271 cases, because 5 of the 276 of which the former tables are composed had no age given.

The following particulars may be gathered from it :—

Of 216 males 110 were amputations for disease, and 106 (nearly one half) for accidents. Of 55 females 41 were for disease, and 14 (about a fourth) for accidents.

Of 110 males for disease there were

| Cured. | Died. | Deaths to Recoveries, as |
| 81 | 29 | 1 to 28 |

Of 41 females there were

| Cured. | Died. | Deaths to Recoveries, as |
| 34 | 7 | 1 to 4·8 |

exhibiting a proportion decidedly in favour of females.

Of 106 male amputations for accidents there were

| Cured. | Died. | Deaths to Recoveries, as |
| 47 | 59 | $1\frac{1}{4}$ to 1 |

Of 14 females for accidents there were

| Cured. | Died. | Deaths to Recoveries, as |
| 10 | 4 | 2 to 5 |

again giving a result in favour of the females.

Table shewing the number of amputations at different ages (including males and females) with the proportionate mortality.

Ages.	Numbers.	Cured.	Died.	Deaths to Recoveries.
From 1 to 10	15	11	4	1 to $2\frac{1}{2}$
10 20	48	43	5	1 to $8\frac{3}{5}$
20 30	33	23	10	1 to $2\frac{3}{10}$
30 40	30	22	8	1 to $2\frac{1}{4}$
40 50	15	10	5	1 to 2
50 60	17	6	11	2 to 1 nearly.
60 70	8	4	4	1 to 1

The rate of mortality for the ages between 9 and 20 is by much the most favourable (1 to $8\frac{3}{5}$), while that from 50 to 60 is the least so (2 to 1); with the exception of those from 60 to 70 (1 to 1), all the others vary only from 1 to 2 the highest, to 1 to $2\frac{3}{4}$ the lowest.

The ages from 10 to 20 afford the greatest number of amputations for disease; those from 20 to 40 the greatest number for accident.

Causes of death in amputations.—I have been able to procure pretty accurate pathological accounts of 73 deaths after amputation, all occurring in the hospital. I have arranged them as follows:—

ewing the causes of death in 73 amputations, the limbs amputated, and the number of days each case survived.

	Primary.	Secondary.	Diseased.	Shoulder.	Arm.	Thigh.	Leg.	Total.	Number of days each case survived.

condary external abscess .	0	0	1	0	0	0	1	1	31
	32	24	17	2	16	35	20	73	

From this table it appears that of 73 deaths, of whose causes and pathology more or less accurate records are given, 32 were primary, 24 secondary, and 17 disease. I have divided the causes of death into, 1st, causes independent of secondary inflammation; and 2d, the various kinds of secondary inflammatory affections.

Of the 8 causes enumerated belonging to the first class, 4 caused one death each, and need not detain us; of the other four, exhaustion, shock, and complication of injuries, caused 11, gangrene of the stumps 6, secondary hæmorrhage 4, and diffusive inflammation and erysipelas 4. It is remarkable that of these 25 deaths 22 were from accidents, and 3 from disease—of which three, two were caused by secondary hæmorrhage. It is highly probable that the 16 cases of exhaustion and gangrene mainly owed their fatal termination to the great severity of the accidents which rendered amputation necessary, aided by the severity of the operation. This is confirmed, first, by the number of hours and days which each case survived the amputation (four did not survive one day, and the longest period is seven days); and, second, by the part amputated (of the sixteen, fourteen were thigh, two leg). The diffusive inflammation and erysipelas were probably owing to the severity of the injury, and the air of the hospital. I was surprised to find that so few of the fatal terminations are attributable to these causes: of the four, three were arm, one thigh.

Secondary inflammations.—In this class, besides those pathological states which are almost universally acknow-

ledged to arise from what is usually styled secondary inflammation, I have included "rigors" and "diarrhœa," the former because I have no doubt that the rigors were symptomatic of secondary disease, and the latter because I believed that ulceration of the intestinal mucous membrane causing diarrhœa belongs to the same class of affections. Of the seventy-three deaths forty-four belong to secondary inflammation, and twenty-nine to other causes, shewing that secondary disease exceeds all other causes of death combined, very nearly in the proportion of five to three. Of these forty-four, nineteen were primary, eleven secondary, and fourteen diseased.

As this subject, secondary inflammation, is one of vast importance, I may, perhaps, be excused if I state what appear to me to be a few facts connected with it. First, as regards their history, I believe they are much more common now than they were thirty or forty years ago. My reason for saying so is, that amputations were then much more successful than they are now, which could not have been the case had these fatal secondary inflammatory diseases been as frequent. If I were asked to assign the probable cause, I should say that it is because those amputations were performed at a much earlier stage of disease, and on patients comparatively in good general health ; second, they are infinitely more common in hospitals than private practice. A large proportion of our hospital surgical deaths arises from them, while in private they are rare. The reason here is obvious— the air of the hospital debilitating the constitution. Third, the more severe the person's disease or injury, and the more the system has suffered, the greater is the liability to these affections. This is almost a corollary on the fact just stated. Fourth, the more severe the operation, the more liable is the patient to secondary inflammation. Of the forty-four cases, fourteen were thigh, seventeen leg, two shoulder-joints, and eleven arm. Not one of the amputations of the forearm was followed by secondary disease. I am well aware that these secondary inflammations occasionally follow very trivial operations and injuries. I have lost two cases of fistula in ano from this cause, and more than one injury of the feet and hands, but these were all in

hospital, and were probably attributable to the atmosphere. Fifth, there is a strong tendency in surgical disease to localize itself in some important internal organ, especially the lungs ; and this is most apt to occur in the feeble and exhausted—in many cases I believe a very short time before death. I believe that a careful examination would shew that the majority of those patients who die of discharge and exhaustion exhibit these affections, and that they are most liable to occur when the discharge is most profuse. I am well aware that profuse discharge [*], or even an open sore [†], is by no means necessary to their formation ; but I feel satisfied that a statistical investigation would shew that a great majority occur during the continuance of profuse unchecked suppuration. In cases where there was no discharge, and little, if any, pus secreted, I have remarked the presence of lobulated pneumonia without deposit of pus.

I have introduced the above remarks principally with the view of making them bear on what appears to me a retrograde movement in the treatment of stumps of late years becoming fashionable—union by the second intention— a proposal sanctioned by the hope of preventing secondary inflammation after amputations. If the above statements are correct this method of treatment rests on very false principles, and cannot be too soon reconsigned to that oblivion in which, in Great Britain, it slumbered for so many years. I believe in all cases union by the first intention, by avoiding the risks of a supurating stump, diminishes "pro tanto" the dangers of an attack of secondary disease.

To this view it is objected that many patients who suffer amputation for disease profusely suppurating, die within a few days of the performance of the operation, apparently in consequence of the sudden check given to the discharge. In a great many of these cases I am convinced that the secondary inflammation existed before the operation, and that it was the failure of strength, caused by these latent inflammations, which induced the surgeon to perform an operation which their presence rendered altogether fu-

---

† Paterson—abscess of prostate, 18th July, 1831.

tile. I do not think we are yet sufficiently alive to the impropriety of amputating after the occurrence of rigors. Almost as certainly as we do amputate our patient dies. We are still less alive to the impropriety of amputating after some symptom previously mild has become suddenly aggravated. It is too much the practice to wait for some occurrence so urgent as to *demand* removal of the limb. Now the very urgency of the symptom, especially if of sudden accession, is often the strongest of all reasons for not amputating, as it too frequently depends on secondary disease, which will certainly destroy our patient whether we amputate or not.

Experience has confirmed my objections to union by the second intention. The cases in which I tried it, certainly few in number, died of phlebitis and secondary inflammation in their most acute forms. Every operating surgeon knows that no amputations so readily unite by the first intention as those of the forearm. In our tables they have been entirely exempt from secondary disease. Again, amputations " below the knee" seldom unite without suppurating. By the tables, when performed " for disease," they are our least successful operations.

These remarks are not intended to apply to chronic suppuration of many months' or years' continuance, in which, as in the case of old ulcers of great extent, amputation is occasionally performed for the removal of an inconvenience, not for the preservation of life.

But even in these an artificial discharge, by seton or caustic issue, is infinitely preferable to " union by the second intention." I may add that our experience of the results of amputations in these cases has not been such as to tempt to a repetition of the operation.

OPERATION FOR SPINAL DISTORTION.

To the Editor of the Medical Gazette.

Sir,

The following account contains a few particulars of an operation which I performed on Wednesday last, the 25th inst., for the relief of spinal distortion. Should you think it sufficiently interesting, as the operation is as yet somewhat novel, I should feel obliged if you would do me the favour to insert it in your next number.—I am, sir,

Your obedient servant,
James Whitehead.

133, Oxford St., Manchester,
Nov. 30th, 1840.

Mr. W. P. J., a young gentleman twenty years and eight months old, son of Major J., of the —th regiment, was placed under my treatment, in February last, for a deformity of the back. He was then suffering from severe palpitations, which became alarmingly aggravated by exercise even of the most moderate kind. His general health was also in a very deranged state, the appetite being impaired, tongue foul, sleep unsound and unrefreshing, pulse weak and irregular, and his strength so feeble that it was with the greatest difficulty he could walk from the office in which he was employed to my house, a distance of about three-quarters of a mile. By the aid of medicines his health was in a short time restored, and he was soon in a fit condition to be put upon certain gymnastic exercises, with a view to relieve the distortion. In two or three weeks more the palpitations had entirely left him, and his strength was greatly improved, so that he could bear to exercise himself actively in the gymnasium for an hour together, or walk six or seven miles without feeling overfatigued. From the time when he commenced the exercises (about the middle of March) to the end of August, his stature had increased one inch and a half. Since then the exercises have been partially, or almost entirely, omitted, and the improvement has ceased to go on. Indeed I fear he has a little diminished in height since the beginning of Oct. I suggested to him a few weeks ago the operation of division of some of the muscles of the back as likely to afford some relief. By partially or totally destroying for a time the action of those muscles which maintain the spine in its present position, we should at least be enabled to employ artificial means with a greater chance of success, and also bring into more efficient play certain other muscles which may assist in rectifying the evil. I explained to him that whatever benefit might accrue from the operation could not possibly be immediate, as the spine, from its anatomical conformation, could not be

as effectually acted upon by mechanical means, even when its restraints are removed, as one of the joints of the extremities: still, as the exercises had already produced such a decided improvement, that there were strong grounds for believing that much might be anticipated from the after-treatment. He consented with great willingness to have the operation performed, and hoped it might be proceeded with as soon as possible.

The deformity consists in a simple lateral curve to the right side, of considerable extent, and involving more than half the spinal column, commencing at the sixth cervical, and terminating at the second lumbar vertebra. A cord extended between these two points would complete it into a segment of at least two-fifths of a circle. It is not, however, quite regular in its form from beginning to end, the curve being more decidedly expressed above than below. The back of the chest on the left side is much flattened, the ribs being nearly horizontal in direction, and their angles scarcely perceptible; while, on the opposite side, the angles are prominent, and each rib so rotated upon its attachment at the side of the spine as to bring its body into a very oblique direction—almost approaching to the vertical, at its back part. The angles of the ribs appear to be somewhat more bent than natural; but this is not so certain. The whole together, and the scapula, which is raised above its natural position, form a very considerable protuberance; and this is increased in appearance by the neck being bent forwards and to the opposite side. The sulcus for the lodgment of the dorsal muscles is obliterated on the right side, and the muscles themselves so attenuated as to be almost imperceptible; while those on the left are full and firm, and more than ordinarily developed. The muscular system in general is strong and well expressed. The deviation from its normal shape of the other parts of the chest corresponds in a measure with those already alluded to. The right side in front projects, and is a little elevated; the left is depressed, and the sternum approaches to a parallel direction with the dorsal spine.

The disease was first noticed in a slight degree about eight years ago, but did not create any particular alarm

among his friends for three or four years after its commencement, as he was all this time in delicate health, the restoration of which it was thought would entirely rectify the deformity. It was observed to make more rapid progress during the three following years of close application to study at College; and his present sedentary employment in the study of the law has been rather favourable than otherwise to its increase. Another circumstance ought to be mentioned as having in all probability contributed—perhaps may have originally determined the direction of the curvature, namely, regular sword exercise, which formed a part of his early education, as he was then intended for the army. This, of course, was suspended as soon as the evil was discovered. He has been under medical and surgical treatment ever since the manifestation of the above-noticed symptoms, having consulted several eminent practitioners both in London and elsewhere. In the early stage of the disease he suffered much from pain in the head, for which he was repeatedly leeched and blistered.

The objects which I had in view by the operation were to release the concavity of the curved part of the spine from the action of some of those very powerful muscles already alluded to, namely, the sacro-costalis (sacro-lumbalis) and longissimus and spinalis dorsi; and by this means to take off the most powerful resistance to the action of others which may be brought into play directly upon the diseased part: as the trapezius and rhomboidei of the same side; and also to enable one to operate by artificial contrivance with better effect.

The operation was performed in the presence of Dr. Pendlebury, one of the physicians, and Mr. Fawdington, one of the surgeons, to the Royal Infirmary, and three other medical gentlemen. The patient was seated in the reversed posture on a low-backed chair, the body bent forwards, and the arms and head leaned over the back of the chair. A portion of skin opposite the seventh or eighth dorsal vertebra was pinched up and divided, and the shining fascia at once brought into view. A straight sharp-pointed bistoury was then passed between the skin and fascia as far as the spine, and the mass of muscle divided by depressing the instrument

slowly and carefully, and at the same time withdrawing it. The bistoury was then again introduced through the same opening in the skin, and passed outwards on the surface of the corresponding rib, so as to divide the attachment of the sacro-costalis as well as the other slips of it going to the ribs above. The muscular fibres separated with a distinct snap, audible to every one present. Mr. Fawdington's expression was, that the sound set his teeth on edge. It was like the separation of a tight bow-string composed of a fascicle of strong threads. Another small incision was made opposite the third vertebra of the same region, and the muscles coming down from the neck divided in the same manner. No outward incision was made at this part. The external openings were closed by slips of plaster, and a compress of lint applied and secured by a bandage. The patient then got up and walked to bed with facility. He was placed on his back upon a hard mattrass formed into an inclined plane. There was considerable difficulty of breathing experienced immediately after the operation, arising, as was afterwards ascertained, from spasm of the posterior intercostal and dorsal muscles of the right side. This was relieved by a powerful anodyne draught, and he continued tranquil and easy two or three hours. I was not able to see him again until seven hours after the operation, when I found the difficulty of breathing very urgent, and was told it had been so for three or four hours. On placing my hand on the back part of the chest, near the spine, on the convex side of the curve, the intercostal muscles were pointed out by the patient as being the principal seat of the pain he complained of, and the erectores spinæ of the same side were more tense than I had before felt them. The latter, he told me, had been affected by cramp, which had several times been very severe, ever since the operation, and also with a constant quivering motion, which could be very distinctly felt by the hand when placed upon the part. A grain of opium was ordered to be taken immediately, and to be repeated every three hours if needful. He passed a very comfortable night, and on the following morning the spasms returned in the same manner, and continued all day; but not so severely as before. A grain of opium was prescribed, to be taken at bed-time. On the third day, as the patient was quite comfortable, and felt no pain in the parts, even when he raised himself into the sitting posture, which he could do with perfect ease, a little gentle traction was exercised on the spine, which showed that the column was certainly flexible, and promised fair for at least a partial, if not a complete restoration. This was done by fixing the pelvis and upper part of the chest by bandages, towards the side of the convexity, and bringing the rhomboidei to act on the hollow of the curvature, the patient lying in the prone position. The same effect was produced by a person being seated on a chair, level with the bed, and pulling at the left arm, having at the same time one foot fixed against the side of the pelvis, and the other in the axilla. During the last two days friction with salt and water and the hair glove has been practised over the dorsal muscles of the right side, which continue to act in the manner before mentioned, and increase in size. The patient's health has not suffered in the slightest degree.

The progress of the case shall be detailed hereafter if deemed of sufficient interest.

SLING FRACTURE-BED.

To the Editor of the Medical Gazette.

Sir,

Among the various contrivances introduced within the last few years for the treatment of fractures, there is one which I feel convinced has not yet been properly appreciated by surgeons: I mean that invented by Mr. Thos. M. Greenhow, one of our most intelligent surgeons in this town. This sling fracture-bed possesses some immense advantages over those now in general use. I shall give a few rough notes of two cases I attended with my friend Mr. A. Davison, of Cramlington, and who authorizes me to express his unqualified approbation of the instrument. I shall then make a few remarks, from which I hope to show that this splint or sling fracture-bed really has many advantages not to be found in other inventions of a similar nature.

CASE I.—Mathew Cleugh, aged 13, received, June 8th, 1840, while at work in Cramlington Colliery, a compound fracture of left leg, about midway between the ankle and knee. The fracture was extremely oblique, and a considerable portion of tibia was forced through the wound. He was immediately seen by Mr. Davison and Mr. French, who reduced the fracture, and placed the leg in one of M'Intyre's splints.

The case at first did well, but we soon found that it was impossible to prevent contraction ; and though extension was repeatedly made we could not maintain the bones in apposition. A period of about eight weeks was spent in unavailable attempts to promote union and prevent contraction, though every thing that afforded a chance of producing the desired effect was tried. I then determined, as a " dernier ressort," to give Mr. Greenhow's " fracture-bed" a trial ; and, in order that it might be properly applied, requested him to go out with me and superintend the application, which he very kindly did.

The leg at this time was a good deal swollen and inflamed, the inflammation being evidently of an erysipelatous character. The wound was covered with high flabby granulations, and looked exceedingly unhealthy.

On the third day after the leg had been placed in the " fracture-bed," there was a remarkable change in its whole appearance : the high granulations were much less, and the swelling and inflammation greatly abated. From this time the leg rapidly improved, the discharge gradually ceased, the inflammation disappeared, and the wound healed. In five weeks we removed the apparatus, as firm union had evidently taken place.

On the 23d of September (when the above notes were made) the boy was walking about on his crutches in excellent health ; and on the next accurate measurement I was unable to detect the slightest shortening when compared with the other leg.

CASE II.—Mathew Beald, æt. 11, had his left tibia fractured about three inches above the ankle. The accident occurred on Wednesday, Oct. 28, 1840, and was occasioned by a stone falling upon him from the roof of the mine.

There were extensive lacerations on the anterior and posterior parts of leg immediately around the fracture.

The limb was on the following day placed in Mr. Greenhow's fracture-bed, and has continued to do well up to the present moment. Firm union has taken place, the wounds have almost entirely healed, and the boy's health, with the exception of a slight attack of scarlatina, has not in any way suffered.

REMARKS.—Every one who has read Case I. must (I think) agree with me that Mr. Greenhow's splint was in the highest degree beneficial ; but I will go further, and state that I attribute the preservation of the limb to the use of this treatment, as the boy's health was beginning to succumb under the irritation the riding of the fractured portions of bone had produced, and the great discharge of matter. All bad symptoms, however, soon ceased, when extension and perfect rest of limbs were obtained.

In Case II. I am not aware of any other contrivance which would have enabled us to dress the wounds, and yet allow the leg to remain in the same position. We have thus been able to clean and dress extensive lacerations during one entire month, and yet the limb remains in the identical position in which it was originally placed. Having mentioned this fact I need not use any argument to shew the ease and comfort experienced by the patient in this mode of treatment.

If this instrument possessed no other advantage, it would still be found to be a most valuable one to the surgeon who lives at a distance from his patient ; for having once fixed the limb in it there is little fear of displacement. I have also found that the friends might with perfect safety be allowed to dress the wounds, and thus save many long and disagreeable journeys.

I fear, sir, that I have already occupied too much space in your valuable publication, and therefore will not extend my observations. The importance of the subject must be my excuse for their present length.—I am, sir,

Yours respectfully,

H. G. POTTER, F.L.S., &c.
Surgeon.

UTERINE HÆMORRHAGE.

To the Editor of the Medical Gazette.

Sir,

On reading the remarks of Mr. Adams on uterine hæmorrhage in your journal of the 30th October, it forcibly struck me that I had met with a similar case. If you consider it worth inserting, you will oblige

Your obedient servant,
W. B. Parkes, M.D.

42, Carnaby street, Golden square,
Nov. 23, 1840.

In October last a friend of mine was called to a married woman (aged 26, of good constitution, who had borne three children before), on account of sudden and frequent gushes of hæmorrhage in the eighth month of pregnancy. She retired to bed about ten o'clock perfectly well, awoke about three by sharp pains in the back and stomach, and found, to use her own words, that she was swimming in blood. My friend applied the usual immediate remedies on such occasions, thereby arresting the return of the hæmorrhage for three hours, at which time it came on again to an alarming extent. He then requested me to see the case with him : I did so, made an examination, and found what Mr. Adams has described in the following words :—" Instead of finding the os uteri in its ordinary state I discovered a large mass of substance, which from its feel I took for a portion of the placenta." My friend made another examination, and concurred in the opinion that it was a case of uterine hæmorrhage, from the placenta being situated over the os uteri. Knowing the general fatal results of such cases, and as the flooding had in a degree subsided, I suggested the propriety before we proceeded further of taking the opinion of a medical man who resided in the neighbourhood, who had been in practice some twenty or thirty years. He made a careful examination, and confirmed my friend's and my own opinion that it was a placenta case, of which he felt not the least doubt. My friend considered it necessary to call in the assistance of that excellent practitioner, Dr. Robert Lee, of Golden Square; he immediately attended, and after a careful examination, gave it as his opinion that the placenta did not present, and what we had taken for placenta was a coagula of blood. Dr. Robert Lee (to our satisfaction) decided that the operation of turning was not at all necessary, and if the membranes were ruptured the case would do well. The membranes consequently were ruptured ; labour pains came on, and in six hours she was safely delivered of a dead child.

ANALYSES and NOTICES of BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'Alembert.

Practical Observations on the Pathology and Treatment of Stricture of the Urethra, with Cases. By Robert Wade, Senior Surgeon to the Westminster General Dispensary, &c. London, 1841. 8vo. pp. 149.

Our author has divided his book into seven chapters. The first consists of general observations ; the others are on the pathology of particular kinds of stricture ; the symptoms of stricture ; the treatment of strictures of the urethra ; directions for the introduction of sounds and catheters ; and the consequences of stricture. The work concludes with an account of twenty-eight cases successfully treated with the potassa fusa.

The following is Mr, Wade's method of applying this remedy :—

"Before using the potash, a bougie should be passed down to the stricture, that its distance from the orifice of the urethra may be correctly ascertained. A small piece of potassa fusa should be inserted into a hole made in the point of a soft bougie. The eighth part of a grain is the smallest and a grain the largest quantity of the potash I am in the habit of using ; but it will rarely be necessary to exceed the sixth of a grain. It will be well to make two notches in the bougie containing the potash ; one, marking the exact distance of the stricture ; the other, an inch beyond ; as, very probably, on introducing the armed bougie the first mark may be concealed within the urethra, from the penis being more stretched than when the measurement was taken. The bou-

gie must be well moulded round the
potassa fusa, so as to prevent the alkali
from projecting; and it should be so
placed that it may be more applied to
the upper than the lower part of the
stricture, for obvious reasons.   Armed
bougies should be well rounded at their
points, to guard the urethra from the
action of the potash before it reaches
the stricture.   In very bad cases it may
be advisable occasionally to use the
potassa fusa in the recumbent position,
as it will then not only be best applied
to the surface of the stricture, but be
most likely to penetrate its texture,
which in old and hard obstructions is
very desirable.   The bougie should, of
course, be well oiled previous to its
introduction."—p. 44-5.

In many chronic cases the potash
may be used every second or third day ;
when greater irritability is present, four
days should intervene.   For the cases
in which it may be used with advan-
tage, we refer our readers to the trea-
tise.

Mr. Wade's book bears the stamp of
sober good sense ; and shews that he
has not allowed his opportunities to
pass away unimproved.

---

*Treatise on the Ear; including its Ana-
tomy. Physiology. and Pathology ; for
which the author obtained a gold medal
in the University of Edinburgh.*   By
Joseph Williams, M.D., &c.   Lon-
don, 1840.   8vo. pp. 255, with six
plates.

This treatise contains an account of the
anatomy and comparative anatomy of
the ear ; and after devoting some space
to observations on sound, and the func-
tions of the ear, our author has usefully
filled more than 150 pages with the
details of its pathology.   Dr. Williams's
book shows a sound judgment, as well
as extensive reading, and encourages us
to hope that he will devote himself to
this branch of practice, and enlarge the
bounds of our knowledge in a domain
which has hitherto been chiefly occu-
pied by puffers and advertisers.   Why
should we not rival the Kramers and
Itards of the continent ?   Dr. William's
essay cannot be read without profit.

---

*A Probationary Essay on the special
Pathology of the Accessory Organs of
Hearing, &c.*   By James Mercer,
M.D., &c.   Edinburgh, 1840.   8vo.
pp. 133.

Our author has divided his essay into
three parts ; the first containing the
general anatomy, pathology, and treat-
ment of diseases of the external mea-
tus ; the second, the general anatomy,
pathology, and treatment of the dis-
eases of the membrana tympani ; and
the third, the anatomical structure, pa-
thology, and treatment of the diseases of
the tympanum and its appendages, es-
pecially the Eustachian tube.

Dr. Mercer's treatise has been care-
fully drawn up, and does credit to his
judgment as well as to his industry.
We trust that he will not remain con-
tent with this preliminary step, but
will energetically resolve to add and
add largely to the stores of professional
knowledge in this interesting branch
of our art.   We wish, in particular,
that he would investigate the statistics
of the diseases of the ear—a department
for which Dr. Mercer's clear style and
impartial criticism especially qualify
him.

MEDICAL GAZETTE.

Friday, December 4, 1840.

SOME DIFFICULTIES IN FORENSIC
MEDICINE.

The very remarkable case of Madame
Laffarge must have awakened every
one's attention to the difficulties which
beset forensic medicine.   Orfila sees a
film of arsenic, where other observers
would perhaps only see a film ; and
Raspail, the staunch controvertor of
certainty in legal medicine, is ready to
obtain as much arsenic from any old
bit of furniture !   However this may
be, it is clear that in medico-legal
chemistry the certain test of 1820 is no
longer the certain test of 1840; and

ho can answer what this will be in
860? Until chemistry becomes a
xed science, and the action of every
ossible combination of substances has
een tried, how can we be sure of our
acts, and confidently prove a negative.

Every story, says the vulgar proverb,
s good, till another is told; and every
est is valid, till a fallacy is discovered
a it. Dr. Christison thinks (or thought,
ome years ago) that the deep-red
olour struck by the permuriate of iron
ith meconic acid was sufficient proof
f the presence of opium. No! says
Ir. Pereira, for two other substances,
hich are likely to be met with in the
limentary canal, produce the same
ffect, namely, mustard and saliva *.

Again, the oil of pimento "produces
red colour with nitric acid, and a
lueish green one with the tincture of
uriate of iron of the Pharmacopœia,
hus agreeing with morphia in two
roperties †."

The saliva produces this effect from
ontaining sulphocyanuret of potas-
ium. On a trial for poisoning, in
829, Dr. Ure was positive that the
tomach contained opium from the
haracteristic colour produced by the
erchloride of iron; and when the
ross-examiner urged this chemical
bjection, he "thought it merely a
use de plaideur."

Can human blood be distinguished
rom other red spots, or from the blood
f animals? The affirmative has been
maintained, but it is highly doubtful.
According to Raspail, Orfila asserted
hat blood might be distinguished from
red spots produced by any other sub-
stance; but Raspail showed spots made
with the albumen of a pullet's egg, in
which he had steeped a small bag filled
with madder; and the effects produced
by the reagents mentioned by Orfila

were exactly the same as if the spots had
been blood.

Orfila then discovered a method of
distinguishing spots of blood from these
artificial stains; for the former, after
being boiled, appeared greenish by re-
flection, while the colour of the latter
remained unchanged. To this Raspail
replied, that tannin and a salt of iron
might be added to the artificial spot in
such a manner that they should not
act on each other till after boiling.
What answer Orfila made to this we
know not. Nevertheless, Barruel soon
afterwards went a step beyond Orfila,
and asserted that sulphuric acid, when
poured on blood, elicited an odour by
which the animal from which it had
been taken might be distinguished.
Raspail the quick soon brought for-
ward his answers to this bold assertion,
and showed that it was easy, by various
admixtures, to give the odour of one
kind of blood to another. Besides
which, Barruel having experimented
on the blood of a small number of
animals only, reasoned from too slender
an induction.

The microscope might seem to afford
a prospect of distinguishing the different
species of blood, but at present this
branch of knowledge is in its infancy.

The celebrated trial of Mr. Angus
for the murder of Miss Burns is a
strong proof of the difficulty of the
science of forensic medicine. Was the
deceased poisoned? She died after
having suffered for about fifty hours
from pain, thirst, and vomiting; and
on dissection a large perforation of the
stomach was found, with pulpiness of
its coats, but no traces of inflammation
about this part. The learned and
candid Beck appears to have altered
his opinion concerning this case, for
in the fifth edition of his Medical Juris-
prudence he says, "With our increased
knowledge on the subject of diseases of
the stomach, it becomes at least pos-

sible that the morbid appearance in question may have been the result of ordinary illness." (p. 753, Note.)

The moral evidence against the prisoner was strong, and if we suppose him to have given the deceased a large dose of mineral poison to produce abortion, all the circumstances of the history will be coherent; but medical witnesses must beware lest they colour their chemical or anatomical evidence to suit the other facts.

It is almost unnecessary to direct the attention of our readers to the treatises of Dr. William Hunter and Dr. Cummin on Infanticide; the former is a defence of the prisoner, the latter will furnish arguments for the prosecution ; but from the natural leaning of judge and jury in such cases to the miserable prisoner, mercy and Hunter are always listened to. It must be acknowledged, too, that the evidence which was ordinarily supposed to be conclusive against the woman was in a high degree unsatisfactory ; and it is very possible that the farther progress of science may throw equal doubt on the tests on which modern medical jurists rely.

We lately touched on the subject of rape ; and we will, therefore, only add to the facts we then alleged—that the medical witnesses on these trials are apt to affirm that on examining the person of the prosecution they found that she had been violated. What do they mean by this ? If they understand merely the signs of recent defloration, this would be intelligible ; but if they mean that they can ascertain by what quantum of violence the girl's resistance was overcome, or whether she offered a real opposition to the supposed ravisher, they surely mean nonsense.

On the whole, it will be allowed that too much is expected from medical witnesses in courts of justice : it is thought that they can draw the finest

line with infallible hand, and show with superhuman tact what deviation from perfect health may be called illness, and what amount of eccentricity just passes the confines of insanity.

But if juries expect too much, witnesses may also give too little. It would not be unreasonable to hope that the profession might furnish some *experts* skilled in the latest refinements of chemistry, and practically conversant with all the details of morbid anatomy. Under the name of district physicians or sugeons, such witnesses might save much annoyance to those who are overwhelmed with the practical details of our art, and while they cleared up many a doubtful point, would reflect glory on the profession from which they were selected.

EXAMINATIONS FOR DEGREES IN ARTS IN THE UNIVERSITY OF LONDON.

WE have thought it right to lay before our readers, at various times, the questions which have been proposed to the candidates for medical degrees and honours in the University of London. Every practitioner of physic is interested, directly or indirectly, in the progress of professional education, and however remote from the scene of learned strife, must be pleased to see what are the last refinements of teachers and examiners in the theory of the art by which he lives.

If medicine, however, is to maintain the rank of a learned and liberal profession, something more is required than a knowledge of the art of healing and ancillary sciences ; and it will be desirable that a considerable number of practitioners shall give some proof of their general acquirements, and be able to meet the other learned professions on equal terms. Hence we apprehend that the examinations for degrees in arts in the University of London must be a subject of interest to many of our readers ; but as they are not so immediately connected with the topics which we usually discuss, instead of giving the papers at

length, we shall content ourselves with a brief notice of them. All the questions before us were set during the present year, and the first series consists of those which formed the pass examination for Bachelors of Arts.

The first paper consists of questions in arithmetic, algebra, plane trigonometry, hydrostatics, hydraulics, and pneumatics. They are easy and judiciously selected: only one question is appropriated to each of the last three subjects, the concluding one being, "explain the construction of the common pump."

Next follow questions on chemistry. The phenomenon of dew, the formation and principal chemical phenomena of a Voltaic circuit, and the constitution of the atmosphere of the earth, are among the topics of inquiry.

We then come to a paper of questions on animal physiology. The circulating system, respiration, the several kinds of nerves, and the uses of the retina, choroid coat, and iris, are among the subjects touched on.

Every friend to the community must rejoice to find animal physiology made a part of general education. Our hopes of the final extinction of quackery rest on the diffusion of this useful knowledge; and even the regular practitioner does not practise the worse, when subject to the enlightened criticism of the educated.*

We then have a paper on structural botany and vegetable physiology,; and then some extracts from the Antigone to be translated, with questions.

The remaining papers are on logic, moral philosophy, Greek and Roman history, and English history; extracts from Tacitus, Massillon, Goethe, and another German author to be translated into English; with English passages to be translated into French and German.

It must be confessed that this examination, which lasted four days, is, on the whole, one of great difficulty; and that any student of one or two and twenty, who could answer half the questions in each paper, must rank as a distinguished man.

Then come the examination papers for honours in mathematics and natural

* Anatomy and Physiology also enter into the plan of education proposed by Lovett and Collins in their late work on Chartism ; and there are questions on these subjects in the lesson-cards of which they give specimens,

philosophy; and another set for honours in classics. Finally, there are examination papers in the Hebrew text of the Old Testament, in the Greek text of the New, and in Scripture History. These appear to form a separate division, perfectly distinct from the other two.

The examination for the degree of Master of Arts is divided into three "branches," namely, Classics—Mathematics—Logic, Moral Philosophy, Philosophy of the mind, Political Philosophy, and Political Economy. Three candidates were admitted to the degree of Master of Arts, one in each branch, from which it would seem that proficiency in one branch alone is sufficient to obtain the degree.

These examinations will undoubtedly be a considerable stimulus to literary and scientific acquirements. At present the number of candidates is but small, as the questions are much in advance of average attainments ; but as time wears on, schools will increase in energy, and, consequently, candidates in number.

ENCOURAGEMENT OF QUACKERY.

The wise and impartial have often differed among themselves as to the quantum of discouragement which it may be advisable to inflict upon quackery. Is it sufficient to withdraw all official countenance from quacks and quack medicines, or is it the duty of the state to inflict punishment on each convicted cheat who trifles with the lives of his fellow-creatures ? Much may be said on both sides of the question; and it might be urged in favour of the latitudinarians, that in a country like ours, great difficulty would practically be found in putting down impostors by force of law. Each freeborn Briton claims the right of shortening his days after his own fashion, and asks why he may not effect his purpose with colocynth and gamboge as well as with gin and whisky ? But it must be confessed that the executive steps out of its way to give encouragement to wrong, when it condescends to mete out the shares of booty between Filch and Bagshot, or settle which proprietor of the Syrian Elixir has the fairest right to poison the public.

Last Monday, November 30th, one

Barker brought his action against a certain Hollier in the Court of Exchequer. Barker sells some stuff which he calls " Atkinson's Infant Preservative ;" while the defendant, not having wit enough to invent a name for himself, obtrudes a nostrum on the unwary with the same title, preceded by the words *Hollier's late* in marvelliously small letters. The plaintiff obtained a verdict with a farthing damages. It strikes us that all men of sense have a right to complain that such a cause should be entertained in a court of justice. As soon as it was shewn that Howqua's tea was made up in London, the Lord Chancellor dissolved the injunction against the person who had imitated the name; and when a plaintiff comes into court as the avowed proprietor of a nostrum, it is absurd to protect him against those who wish to partake in his unhallowed gains.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Nov. 24, 1840.

Sir B. C. Brodie, Bart., in the Chair.

A Case of Osseous Union of a fracture of the Neck of the Thigh-bone within the Capsule. By Walter Jones, Esq., of Stafford. Communicated by Edward Stanley, Esq., F.R.S., &c.

The patient in this case, who was more than eighty years of age, was first seen by Mr. Cole, the House-Surgeon of the Stafford Infirmary, on the day succeeding to that on which the neck of the thigh-bone had been fractured by a fall. Mr. Cole applied a splint to the outside of the limb, extending from the pelvis to the foot, and bound the leg together, the apparatus being completed by a bandage round the pelvis. The patient suffered so much pain, aggravated by a troublesome cough, that he removed the splint and bandages. After having allayed the pain, and quieted the cough, however, by the aid of laudanum, Mr. Cole reapplied the bandages, and retained them in their position six or eight weeks, when the patient was allowed to get up. During the following spring and summer he was able to go about with the assistance of a stick ; but, becoming the subject of chronic catarrh, he died about a year and a half after the injury had been sustained.

The capsule was found much thickened, and it became necessary to divide the shaft of the bone before the knife could be passed

round the joints ; so near had the trochanter approached to the acetabulum. The direction of the fracture could not be traced, or the bond of union made out, until the bone had been macerated. As the portions of capsule became loose, they were removed with the forceps, " which enabled me,'' says the author, " to discover, what I believe to be the case, that the fracture was within the capsule.'' The bone, sawn through, and a very accurate drawing of one of its sections, were shewn to the meeting.

READ ALSO,

Observations on the improper Use of Opium in England. By Julius Jeffreys, Esq.

This paper had for its objects to point out the great and alarming increase (as it appeared to the author) of opium-eating in England, and to solicit from the society some declaration which might have the effect of discouraging such practice. The author depends for his proof of the increase of opium-eating upon the Custom House returns of the quantity of the drug imported into England in each year from 1828 to 1838 inclusive ; by which it would appear that a very considerable increase had been experienced—the quantity entered for home consumption in the former year having been 16,169 lbs., and that in the latter 31,204 lbs.

Before the society adjourned it was ordered that the Council be requested to prepare and cause to be presented to Her Majesty, His R. H. Prince Albert, and H. R. H. the Duchess of Kent, three several addresses of congratulation on the late auspicious event of the birth of a princess.

MEDICAL REFORM BILLS.

To the Editor of the Medical Gazette.

Sir,

The Medical Reform Bill lately proposed by Mr. Warburton, though it has been subjected to much discussion, appears hitherto to have remained an unsolved enigma to the acuteness of all the medical criticism that has been so liberally expended on it. Unanimous opinion seems to have regarded it as altogether a very silly piece of business, inexplicable as to its objects, and inadequate to our necessities. There is, however, a very simple key to the mystery, and a short review of the different acts of government during the last few years will afford a clear explanation of the objects intended by the directors of this otherwise incomprehensible bill. In the general politics of this country the public have been long divided into two great classes, reformers and anti-reformers. Of the agitation resulting from the frequent collision between these two classes our

overnment has taken a shrewd and skilful dvantage, in order to carry out the grand bject they have long had in view, namely, hat of bringing every department of public ffairs under their own direct and immediate ontrol. This system of centralization, as t is called, is the mainspring by which all overnment interference is influenced. For his purpose agitation is encouraged, the najority generally flattered, and the people y this means deceived into a surrender of mportant rights as a sort of compromise for he advantages of reform. This object is pparent in the several acts that have refer-nce to Ireland (for Ireland is the theatre in vhich this experiment is now being tried), n the appointment of a stipendiary magis-racy, the establishment of a powerful police orce, whose ramifications extend in every lirection through the country, in the corpo-ation bill, in the poor law act, and finally n that part of Mr. Warburton's Medical Reform Bill which should invest government vith the power of appointing a certain pro-ortion of the intended medical senate, and nflicting, with discretionary powers, a most injust general medical tax. Now, though I nust acknowledge that members of our profession ought to abstain as much as pos-ible from all interference with general olitics, still it appears to me so important o our main interests at present, to have a clear idea of the principles on which the proceedings of government are based, that I eel myself justified in offering these remarks. If it be true, as I believe it to be, that these principles are not only exceedingly dangerous o the liberties of the British nation, but also, vhen applied to the management of our professional affairs, will place us in a state of thraldom and servitude from which we nay possibly never recover—subject to the caprices of secretaries of state, and the con-rol of men utterly ignorant of the wants of our profession—then, sir, I conceive that I need no apology for thus endeavouring to draw attention to points so material, in order that, at least, we may discuss, with our eyes open, this plan of centralization now artfully concealed under the title of medical reform.—I am, sir,

Your obedient servant,
E——.

Dublin, Nov. 18th, 1840.

MINERAL WATERS.

I always return to the same point, which I have often mentioned already, that mineral waters form a large and quite peculiar class of natural productions and agents, and that our chemistry is far from being able to de-termine their composition, their value, or their worthlessness. It can say nothing more than—the analysis of the water, ac-cording to the present state of chemistry, gives the following results and products, which we allow ourselves to call educts. But then, I just ask, was the substance, which you found after analysis, really in the water, or did it arise from the analysis, and the influence of external agents necessary for the analysis; and was it, consequently, a product instead of an educt? Moreover, if these substances were contained in the water, did they exist there in the shape and form in which they are now seen after analy-sis; and does not more depend on the combination of the elementary substances, than on their separate nature? What a wide difference is there in the effects of the same substance under different forms—solid, fluid, and gaseous; as, for instance, in the effects of ice, water, and steam. Can we properly say that we know a substance in its living being, when we know its skeleton? And, more or less, every chemical analysis is nothing beyond this, as it gives us merely the products of processes of decompounding, that is, of destroying. For not organic bodies alone, but inorganic ones also, have their living existence. How different are the various kinds of wine! Würzburger, Hochheimer, Johannisberg, Thuringian, Burgundy! The palate of the connoisseur, and their different effects on the frame, dis-tinguish them well enough; but to chemis-try they are all wine, and not remarkably different in their elements. Granting, how-ever, that we were to give up all this, even then we could only say that, according to the present state of chemistry, such or such a substance contains such and such ingre-dients. But does it follow that it cannot contain any others? By no means.—*Hufe-land. Priktische Uebersicht der vorzüglichen Heilquellen Teutschlands.*

MILITARY FLOGGING.

On the same day, on the third reading of the Mutiny Bill, Sir Francis Burdett pro-posed a clause to abolish the punishment of flogging in the army. I was one of only eight, including the tellers, who divided with him in support of the clause. I spoke too in support of it; and in the course of my speech I vindicated my friend Brougham, who had been accused of making a most extravagant and exaggerated statement, be-cause he had said, on a former occasion, that, for very serious offences, it would be better to punish soldiers by shooting than by flogging them; and I mentioned what I had read a few days before in the *Trans-actions of the Missionary Society.* In the journal of one of the missionaries at the Cape of Good Hope are the following passages:—
" July 14, 1810. A soldier belonging to

the Cape regiment had been tried for desertion, and was condemned to die." It then proceeds with an account of his being attended by one of the missionaries, and his conversion previous to his being shot. " Another, who had been also guilty of desertion, and who was to receive 1000 lashes, appeared more impressed. He received but 224 lashes, the surgeon judging that he was not able to bear more, and thus he was for this time freed. Being brought to the hospital, he remained there some weeks, and died. Brother Read, visiting him before his dissolution, gave us likewise hope of his salvation." *(Transactions of the Missionary Society,* vol. iii. p. 392).

The facts are here mentioned without any observation, and are preserved only incidentally, and as necessary to state what is the business of the journal, the successful spiritual labours of the missionaries.

We have here, for the more aggravated crime, a criminal simply deprived of life ; and for the slighter offence, another put to death with exquisite tortures, and by his sentence doomed to suffer four times as much misery as God had given him a capacity of enduring. Who can doubt that in this instance, and in many more which have occurred, a sentence of death would have been a sentence of mercy ?—*Sir Samuel Romilly's Diary,* March 1812.

EXCESSIVE BLEEDING.

THUS we find a great many errors committed in prescribing for this sort of people, upon the presumption that their robust constitutions will bear stronger remedies than the inhabitants of towns. I am oftentimes moved with compassion, when I see the poor country-people brought into the public hospitals, and committed to the care of young physicians just come from the schools, who utterly exhaust their strength with strong cathartics and repeated phlebotomy, without any regard to their being unaccustomed to strong medicines, and enfeebled with labour and fatigue. And 'tis for this reason that many of these poor wretches choose rather to die peaceably in their country huts, than to lose their lives in the hospitals after the oppression of bleeding and physic. In *Campagna da Roma,* as soon as reaping is done, the hospitals of Rome are crowded with reapers and day-labourers ; and 'tis a doubtful question whether the surgeon's lancet, or the sickle of death cuts off most reapers.—*A Treatise of the Diseases of Tradesmen.* Written in Latin by Bern Ramazzini, Professor *of* Physick at Padua, and now done into English. London, 1705.

HOW TO IMPROVE WINES.

WEAK wines, and those that have been too long fermented, are very apt to become sour ; but the acidity may be corrected by the addition of sugar ; or more effectually by neutralizing the acid. For this purpose the alkalies and alkaline earths, especially lime, have been employed. It was formerly the practice to use the acetate of lead to destroy the acidity in weak wines, but this murderous practice has long since been laid aside [?].

Ropiness may be got rid of by exposing the bottles to the sun and air, by adding a small quantity of vegetable acid, and by fining. The *mustiness* and other ill flavours communicated by the casks or cork, may sometimes be removed by agitating the wine in contact with the air, or by the introduction of common carbonic acid gas, by pumping.—*Miss Burnett's Illustrations of Useful Plants,* September, 1840.

Wind N.E. on the 25th, and two following days ; North on the 28th, and morning of the 29th ; afternoon and evening of the 29th East ; since S.W.

On the 25th and two following days generally clear ; the 28th and 29th foggy ; the 30th ult. generally overcast, a few drops of rain fell during the afternoon; the 1st inst. generally cloudy, rain in the morning.

We have, as on the 16th ult. again to remark upon the extraordinary change in the temperature, viz. on the 29th of November, and following day, an increase of thirty-one degrees.

CHARLES HENRY ADAMS

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture XII.

Varieties of Inflammation; acute and chronic; latent; specific. Scrofulous inflammation. Tubercles. Relative frequency of scrofulous disease in different organs. Signs of the strumous diathesis.

WE have now, gentlemen, considered the phænomena of inflammation, local and general: its symptoms and its events; and the indications of these afforded by the state of the system at large: and we have surveyed the principal tissues of the body, and observed the modifications and peculiarities to which the process of inflammation is liable, according as it is situated in the one or the other of those tissues.

Acute and chronic inflammation.—There are still some varieties of inflammation; and some epithets applied to inflammation; which require to be explained.

Acute, and *chronic*, inflammation: these are words perpetually in our mouths. I have frequently employed them already. What do they mean? Is acute inflammation different from chronic in *kind?* No: they differ only in *degree*.

When the disease runs its course rapidly, and is attended with much general as well as local disturbance, it is said to be acute. When, on the other hand, the local and constitutional symptoms are less violent, and the inflammation runs a longer course, its phænomena following each other in slower succession, it is said to be chronic. The process is the same, but its features are less strongly

expressed. The disease passes through similar stages in both cases, but it travels at a different pace. The characters, then, of acute inflammation are intensity of symptoms and rapidity of progress: and the characters of chronic inflammation are mildness of symptoms and slowness of progress. Inflammation can scarcely be very violent, and at the same time of very long duration. When violent it has been likened (by Mr. Lawrence, whose language I have here adopted,) to a fire, which soon burns itself out. It may, however, be mild in its symptoms, and yet quickly over. The two terms acute and chronic are not directly opposed to each other: acute has more relation to the intensity, chronic to the duration of the disease; and some term is wanted—although it is hardly worth seeking for—to denote such a degree of inflammation as exists in a pimple; which is neither severe nor long continued.

Now, in respect to intensity and duration, there are almost infinite shades of difference in different cases of inflammation; and the same difficulty occurs here which always occurs when general terms are employed to express mere differences of degree. We feel no uncertainty or hesitation about those cases which occupy the two extremes of the scale; but with regard to those which lie in the middle we are often at a loss. To meet this difficulty some pathologists have invented a third term, viz. *sub-acute* inflammation, intending thereby to designate cases which hold an equivocal rank; which are neither decidedly acute nor plainly chronic; in which the inflammation may run a brief course, and be attended with a certain degree of fever; but attains no great intensity, effects no profound changes, and does not require very energetic remedies to control it.

You must not suppose that, because chronic inflammation is attended with less violence and disturbance, it is necessarily on that account less dangerous or destructive than acute. The latter is commonly more

under the influence of remedies than the former : it is usually soon brought to an end : whereas chronic inflammation is often obstinate and abiding, and leads to very serious changes in the part upon which it fastens.   Speaking generally, it tends to thicken and indurate when it is situated in the *interior* of organs, and to the effusion of pus when it affects *membranes.*   It is more common in weakly and debilitated persons than in others : but we must not forget that such persons are also very liable to acute inflammation.

Chronic inflammation is not unfrequently a *sequela* of acute inflammation.   And that the two merely differ in degree, and not in kind, is evident from this : that acute inflammation may sink or subside into chronic ; and that, on the other hand, chronic inflammation may readily be aggravated into acute.

There is another distinction of inflammation into *active* and *passive*, which is less intelligible.   I believe that they who use the term passive inflammation intend to signify by it that languid and sluggish kind of inflammation which is apt to occur under the same circumstances, and in the same conditions, with passive *congestion*.   When the granulations of an ulcer are in that state in which they may be made brighter, smaller, and healthier, by the application of a stimulus : when the blood-vessels of the eye are left, after acute inflammation, turgid and tortuous ; and that condition is improved, instead of being worsened, by the use of a stimulating lotion : in such cases as these, some persons would say there was passive inflammation.   But I see little difference between this and chronic inflammation ; nor do I know any difference between *active* and *acute* inflammation.

Latent inflammation.—The term *latent* inflammation is one of modern introduction. It is applicable to those cases in which internal inflammation runs its course silently, insidiously, and unperceived ; without the usual warning tokens of its presence ; without its more striking and prominent signs. Pneumonia, going on to disorganization of the lung, may arise, proceed, and even prove fatal, without any of the symptoms which ordinarily announce that disorder : without notable cough, or obvious dyspnœa, or complaint of pain, or the expectoration proper to pneumonia.   And the same is true of other inflammations.   We discover, with surprise and horror, the traces of their operation, when we come to examine our patient's dead body.

This is a most important form of inflammation ; for though it does not declare itself to ordinary observation, neither does it occur absolutely without symptoms : but it requires that the symptoms should be looked for.

The *auscultatory* signs of pneumonia, all those symptoms which are furnished by the physical condition of the affected organ, are present, and speak as clearly as in the more flagrant cases.

Latent inflammation is apt to creep on during the progress of certain disorders, whereby it is modified and masked.   It belongs to those states of the system in which the sensibility is dull, and the vital powers languid.   In continued fever not only have I known the lung pass into suppuration, when the existence of pneumonia had been unsuspected ; but I even have seen one case in which that usually torturing accident, perforation of the bowel, took place, with the escape of its contents into the cavity of the abdomen, and extensive peritonitis—yet the patient expressed no sense of pain, and the inflammation was revealed, while he continued to live, by no intelligible symptom.

Inflammation of this insidious and lurking character is most to be apprehended in the aged, in those who are habitually intemperate, and in persons of sluggish temperament.   It sometimes occurs during convalescence from acute diseases.

Specific inflammation.—Besides the varieties which have been mentioned in degree, there *are* also differences in *kind* among inflammations.   What I have been speaking of during the preceding lectures I have called common inflammation.   It is the *most common* form in which that process displays itself.   All persons are liable to it ; and that again and again.   None are at any time privileged from its attacks.   But there are several forms of inflammation different from this, which are called *specific.*   There are various forms of specific inflammation affecting the skin, discriminated from each other by the local appearances they exhibit, and by the constitutional disorder which attends them.   The rash, and the fever, of measles, are very unlike the rash and the fever of scarlatina ; and both differ remarkably from those of small-pox, the eruption of which consists of little phlegmons.   In each of these diseases the application of a specific poison is required for its production : and whereas common inflammation has a tendency, when once it has happened, to happen in the same part again—to *recur*—these forms of specific inflammation never, or almost never, occur more than once.

There is again the gouty inflammation—differing from common inflammation in several signal respects ; in the production of chalk-stones ; in its attacking those who are descended from ancestors who have had the disease, and scarcely any others.   Then there is rheumatic inflammation, cousin-german to the gouty, yet distinguishable from it.   And

another variety of inflammation is that which arises from the introduction of the syphilitic poison into the system.

Scrofulous inflammation.—Of the specific forms of inflammation now adverted to I shall speak when I come to consider gout and rheumatism, and the contagious exanthemata, as distinct diseases. But there is one variety of inflammation—I mean the *scrofulous*—which meets us on every side; and is apt to affect so many parts of the body, and so great a number of persons; and has so fatal a tendency in most cases; that it cannot be left out of the account that I have been desirous to give you of inflammation in general.

Scrofulous or strumous inflammation (for struma and scrofula are convertible terms) is a *slow* process; it falls therefore within the class of *chronic* inflammations. It is not attended with much pain, or heat, nor for some time with much change of colour; and the redness which does accompany it has often a livid or purplish tinge.

These, however, are the negative properties of merely chronic inflammation. But *suppuration* at length occurs, which also lasts long: and the pus formed is peculiar and characteristic. It is not homogeneous or smooth, but consists partly of a thin serous whey-like fluid, and partly of fragments of a substance resembling curd: and the ulceration that ensues is marked by corresponding peculiarities. The ulcers are indolent; show but little disposition to heal. Scrofulous inflammation, compared with common, or what is called healthy inflammation, is in general but little influenced by remedies.

Tubercle.—Besides this scrofulous *inflammation*, it is necessary that I should now direct your attention to another form of disease, which is likewise properly denominated scrofulous. It is marked by the appearance, in various parts of the body, of what are called *tubercles*. These tubercles are masses of unorganized matter—also resembling curd or new cheese, more or less; but of various shapes and sizes. They suffer gradual changes; soften or break down; undergo a sort of suppuration; and the softer matter into which they thus (as it were) melt, has the characters that distinguish the pus of a scrofulous ulcer or abscess.

Now *tubercles* and scrofulous *inflammation* occur very continually in the *same individuals :* and what is remarkable, although they affect a very large portion of the whole human race, and conduce more often and surely than any one thing else to shorten the natural period of human life, yet they belong, almost exclusively, to certain *classes* of persons. We can tell, beforehand, that such and such persons are likely to become affected with scrofulous inflammation, or with tuber-

cles : and we say of those persons that they have the scrofulous *diathesis*. I will not positively affirm that these forms of disease *cannot* be produced in any or in all persons: but this much is certain—that some persons are particularly prone to them; fall into them as it were spontaneously; on the operation of very slight external causes : while other persons never show *any tendency* to scrofula, even when continually exposed in the same manner: or if they do become scrofulous at all, it is only when the external circumstances most favourable to the production of such disease have been extreme in degree, and protracted in their application.

The occurrence of scrofulous *inflammation* in various parts constitutes distinct diseases; and the occurrence of *tubercles* in various organs constitutes *other* diseases. It will facilitate our future inquiries into these several diseases, if I take this opportunity of stating to you what is known respecting the scrofulous diathesis generally : and of the modifications of inflammation which are determined by its presence.

A good deal of discrepancy, obscuring the whole subject, and puzzling the student, has existed—and I believe I may say still exists—among pathologists, as to the nature, and origin, and precise seat of tubercles, and as to the changes which they undergo.

In general they have been loosely described as being *round* masses of firm friable matter, deposited in various parts of the body. Laennec, who paid great attention to tubercles, states that they are, at first, small, firm, greyish, semitransparent bodies, which enlarge and become opaque. In that condition he calls them *crude* tubercles : at length, after an indefinite period, these crude tubercles begin to grow soft in their centre, and are by degrees converted into a liquid mass, having the consistence of cream. There is a great deal of error in this description.

Andral, another great authority, says that tubercles are, in the outset, small round opaque yellowish bodies, unorganized, and of various degrees of consistence. He ascribes their softening (not to any spontaneous changes in their central parts, but) to the admixture of pus, poured out by the textures immediately surrounding the tubercle; which has irritated and inflamed these textures as any *other foreign body* might.

In some respects this statement is nearer the truth than Laennec's.

But in the account which I am about to give you, I shall chiefly follow our countryman, Dr. Carswell, the Professor of Pathological Anatomy in University College; who is one of the latest, and, as I think, most satisfactory writers on the subject. His opinions were formed after a careful exa-

mination, for himself, of the parts infested by these tubercles. He devoted several years to the study of morbid anatomy, in Paris, where he made a very large collection of drawings, in which various diseased appearances are beautifully and faithfully delineated. Some of these he has since published. I shew you enlarged copies of those which relate to tubercle. They bear out some novel opinions which are stated in the letter-press that accompanies them.

After all, the points in question possess more of curious interest than of practical importance. But as you cannot help forming some notions respecting them, 1 think myself bound to lay before you those which most recommend themselves to my own judgment. At the same time you are to understand that I do not vouch for their absolute correctness.

Tubercles, then — or rather tubercular matter—is deposited from the blood. It may be considered as a morbid secretion. It is probable that the deposit, in the very beginning, is fluid: but we never see it in that state. It is certainly not so firm at first as it generally becomes afterwards ; but its more watery parts are removed by absorption, and then there remains a "pale yellow, or yellowish-grey, opaque unorganized substance." This tubercular matter, so deposited, does not always assume a round form : far from it : the shape in which it appears depends upon the nature of the part wherein it is formed. It used to be held that the tubercular matter was always deposited in the cellular tissue. But Dr. Carswell asserts that its most favourite seat (if one may so speak) is *the free surface of mucous membranes*. In whatever organ it is met with, if mucous tissue enters into the composition of that organ, that particular tissue is either (he says) exclusively affected, or much more extensively affected than any of the other component tissues. These remarks apply to the lungs, the alimentary canal, the liver, the urinary organs, and the organs of generation ; but it is much more easy to detect the presence of the tubercular matter in the mucous tissue of some of these organs than in that of others. It is very conspicuous in the fallopian tubes and uterus.

But tubercular matter is often deposited on serous surfaces also ; among which Dr. Carswell includes the cellular tissue. It is even to be seen sometimes in the blood itself : not indeed while it is retained in its proper vessels, but when it is collected in the cells of the spleen. You know that the spongy texture of that organ allows the blood to accumulate in it in considerable quantity : and the tubercular matter may be seen forming in the blood at some distance from the walls of the cells in which the

blood is contained. In one cell, according to Dr. Carswell, you may perceive simply the blood coagulated : in another, it will be coagulated and deprived of its colouring matter : and in another, converted into a mass of solid fibrin, having in its centre a small nodule of tubercular matter.

Now when a speck or morsel of tubercular matter has been deposited, any where, it is liable to increase. It grows larger by continued accretion ; by additional deposits upon its surface. This being the case, we see plainly enough how it happens that tubercles assume different shapes, according as they occur in different parts. The round form which is so often observed is purely accidental. When a tubercle is deposited in the substance of the brain—and becomes larger by the continual accession of fresh tubercular matter upon and around it—it naturally takes a spherical form, because there is nothing to limit its enlargement, except the soft cerebral matter itself, which presses it with equal force on every side. For the same reason tubercles deposited in the *cellular* tissue are globular. In like manner, if tubercular matter be laid down in one of the pulmonary vesicles, so as to fill it up, it exhibits the rounded form of the vesicle. When it fills the cavity of a mucous follicle, it has a similar figure. But in the smaller bronchi it takes a cylindrical arrangement. When (as often happens) it occupies one of these tubes, and also all the air-cells to which that tube leads, then we have a sort of branch of tubercular matter, with a cauliflower termination. You see this depicted in the drawings before you. In the cavity of the uterus, and the fallopian tubes ; in the infundibula and pelvis of the kidney, and in the ureters ; and in the lacteal and lymphatic vessels ; the tubercular matter is moulded to the forms of these parts respectively. We are more in the habit of examining tubercles in the lungs than any where else ; and you will observe that in making sections of these organs, and looking only at the surfaces of these sections, we may easily overlook the branch-like disposition of the tubercular matter in the smaller bronchial tubes. We see the transverse section only of these tubes, which is necessarily more or less circular. On the surfaces of serous membranes, whether natural or adventitious, the tubercular matter will assume a rounded, or a lamellated form, according as the secretion in which it originates has taken place from separate points, or from a continuous surface.

From what has now been stated you will perceive that no alteration can take place in the tubercular matter after once it has been deposited, except through the agency of the parts around it and in contact with it. It

is never organized, or capable of organization ; and, consequently, no change in its consistence can originate in the tubercle itself.

It may therefore seem odd, that so accurate an observer as Laennec should have persuaded himself that the softening of tubercles begins in their centre.

Now Dr. Carswell has given what appears to me a very satisfactory explanation of this mistake. Take the lungs ; the morbid conditions of which were the most especial object of Laennec's investigations. The tubercular matter is effused (principally) upon the mucous surface ; upon the inner lining of the air-cells, and of the bronchial tubes communicating with them. Now it need not so accumulate as to *fill* these cavities ; and it often does not ; there is left a central cavity, which contains mucus, or other secreted fluids : and if the lung be cut across under these circumstances, the divided air-vesicles will look like rings of tubercular matter grouped together ; and each divided bronchial tube will present also the appearance of a tubercle, with a central depression, or soft central point. On the other hand, when the tubercular matter has completely filled and blocked up these cavities, both vesicles and bronchial tubes will look, when divided, like the section of round solid tubercles. These Laennec seems, in fact, to have regarded as *crude tubercles :* while he mistook the former appearances for tubercles which were beginning to soften in their centre.

But you sometimes find large masses of tubercular matter in the lungs, or elsewhere : and in these masses you see that the process of softening is going on at several points, within the mass, at the same time. How is this to be explained? Why these large masses are formed, in truth, by the aggregation of many smaller masses, which lying near each other, have been pressed together, as the deposit continued to increase : and the cellular and other tissues originally intervening between them at length suppurate, by reason of the augmenting pressure ; and by their suppuration, they soften, and gradually break down the tubercular matter which they enclose, and by which they are also enclosed. This is just the process by which tubercles are frequently expelled from the body. They increase till the surrounding parts take on inflammation, just as they would do if any foreign body exercised the same degree of pressure upon them. The inflammation thus excited is of the scrofulous kind ; the thin pus which it throws out pervades and loosens the tubercular matter ; a process of ulceration goes on in the surrounding textures ; and at length (supposing the lung to have been the seat of disease)

the detritus of the tubercle is brought up, gradually, by coughing.

Both Laennec and Louis, the latter also being a very close observer, describe the nascent tubercle as a grey semitransparent corpuscle. I have frequently seen such : but the appearance is rare, in comparison with the more opaque form of tubercle. Of this, too, Dr. Carswell offers what I think a very probable explanation. He says that the mucous membrane of the air-tubes separates from the blood, not only the matter of tubercle, but also its proper secretion : and that, frequently, when the two have been poured out *together*, a dull yellow opaque point of tubercular matter becomes *set*, as it were, in a portion of grey, semitransparent, and, sometimes, inspissated mucus. The same deceptive appearance is common on serous membranes : in tubercular peritonitis, coagulable lymph exudes, portions of which envelope little globular masses of tubercular matter.

The account which I have now given you, and which I hope I have made intelligible, is, I think, extremely interesting—and much credit is due to Dr. Carswell for having so greatly simplified our views of a subject which had previously been wrapped in profound obscurity. In no other writer, that I know of, is there to be found so complete and credible an explanation of the origin of tubercles ; of the form they assume ; of the phænomena attending their enlargement, and subsequent softening, and occasional expulsion.

These processes of softening, in consequence of surrounding inflammation—and of subsequent expulsion—may be regarded as a natural mode of cure. Such a cure is in truth occasionally effected. A scrofulous abscess will form in the glands of the neck—and pus and tubercular matter will be discharged—and at length the ulcer heals, and no trace of the diseased process remains, beyond a scar : and the same thing takes place also in the lungs ; and, if there have been only one or two masses of tubercle deposited, the patient may thus get quite well : but unfortunately, as the scrofulous matter is extirpated from one part of the lung, it is apt to be multiplied in another, till at length we have death by hectic, and all its melancholy accompaniments.

But I am desirous of pointing out to you another way in which tubercular disease may be said to be cured by a natural process. And this also has been better described by Dr. Carswell than by any other writer. One form of scrofulous disease, exceedingly common too, especially among children, is what is called "tabes mesenterica." Tabes and phthisis, the one a Latin and the other a Greek word, signify, I need scarcely tell you,

the same thing : a wasting away, or consuming : and phthisis is applied to the same disease in the chest, to which tabes is applied in the belly. The common English word is consumption ; and we might very well speak of pulmonary consumption, and of abdominal consumption ; but the technical name of the latter complaint is tabes mesenterica. This is not only a very common but a very fatal disease in children and young persons. The glands of the mesentery enlarge and become charged with tubercular matter : but they very rarely suppurate. Their enlargement is commonly connected with scrofulous disease and ulceration of the mucous follicles of the intestines : and the little patients die, because the lacteals are no longer able to take up sufficient nourishment from the food : they die starved. But some few do recover from tabes mesenterica. Dr. Carswell relates an interesting case in which such recovery took place, and in which he had an opportunity of examining the glands at a subsequent period : it is the only case of the kind perhaps on record. He says, " The patient who when a child had been affected with tabes mesenterica, and also with swellings of the cervical glands, some of which ulcerated, died at the age of 21, of inflammation of the uterus, seven days after delivery. Several of the mesenteric glands contained a dry cheesy matter, mixed with a chalky-looking substance ; others were composed of a cretaceous substance ; and a tumor, as large as a hen's egg, included within the folds of the peritoneum, and which appeared to be the remains of a large agglomerated mass of glands, was filled with a substance resembling a mixture of putty and dried mortar, moistened with a small quantity of serosity. In the neck, and immediately beneath an old cicatrix in the skin, there were two glands containing in several points of their substance, (which was otherwise healthy), small masses of hard cretaceous matter."

Now what Dr. Carswell here saw in the mesentery and the neck, is what sometimes occurs in other parts of the body ; in the lungs ; and particularly in the bronchial glands at their root, and about the bifurcation of the trachea. From these situations, the hard chalky matter left by the absorption of all the more watery part of the morbid secretion, and by the concretion of its earthy salts, is often coughed up. But it may remain, when the tubercles are few, and there is no tendency to their increase, for years, as an inert, and almost harmless mass.

I mentioned just now that the secretion or separation of the matter of tubercle from the blood, takes place, by preference, upon the free surface of mucous membranes, and very frequently also upon the surface of serous tissues, including the cellular.

It may not be uninteresting to state the relative frequency of scrofulous disease in different organs, or in different parts of the same organ. The facts which we possess of this kind afford us very valuable assistance sometimes in respect of diagnosis.

During the periods of childhood and youth the lymphatic glands are exceedingly prone to scrofulous inflammation : especially the mesenteric and the cervical glands. But in adult age tubercles are, beyond all comparison, most frequent in the *respiratory organs ;* and they occupy the summit of the lung much more commonly and thickly than any other part. The superior and posterior porion of the upper lobe is the part in which, if any tubercles at all exist in the lung, they are almost sure to be found : in this situation their softening also commences ; and it is supposed that the left lung is more obnoxious to tubercular disease than the right. So constant is this law, with respect to the upper parts of the lung, that Dr. Carswell considers the formation of tubercles in any other part of the lung as a secondary occurrence ; and he declares it as the result of his experience (and few persons can have had more opportunities of examining diseased lungs) that there is no deviation from this rule ; except when some other portion of the lung may have been the seat of an inflammatory attack, which has determined the priority of tubercular disease in that portion. We shall see hereafter what a very important bearing a knowledge of this law has, in settling the nature of a complaint which might, without it, be doubtful.

Scrofulous ulceration of the larynx and trachea, when they occur, are usually concomitants of tubercular deposits in the lungs.

Next, tubercular or strumous disease is exceedingly common in the digestive organs : most of all in the mucous follicles of the small intestines ; both in those which are separate, and are called glandulæ solitariæ, or Brunner's glands ; and in those which are collected into roundish or oblong groups, the glandulæ agminatæ, or glands of Peyer. It is secondarily to these affections, in many cases at least, that the glands of the mesentery become implicated. Tubercular deposits are frequent also in the solitary glands belonging to the cæcum. The ulceration which follows the evacuation of the strumous matter from these parts gives the interior of the bowel an appearance somewhat resembling a moth-eaten garment. Tubercular matter is seldom deposited in any other parts of the intestines, great or small, than those which I have mentioned. Dr. Carswell supposes that it may often be secreted upon the free surface of the membrane, but that, not being entangled or confined in any mucous crypt, it is removed as soon as it forms. It is not

often that scrofulous tubercles are found in the liver of adults : they are not very uncommon in that organ in children, but even then they are few in number and small in size. It is a curious fact that they are much more frequently seen in the spleen also in children, than in grown up persons. The uterus, the testicle, the prostate gland, are all liable to them : they are common enough upon the surface of the peritoneum.

In the nervous system, tubercles are by no means unfrequent : they are met with oftener in the brain than in any other part of that system. That inflammatory affection, which leads to the effusion of serous fluid in the cerebral ventricles of young children, and is known by the name of hydrocephalus, occurs principally, if not altogether, in connexion with the scrofulous diathesis.

Strumous deposits are rare in the organs of circulation. Tubercles have been seen, I believe, in the muscular substance of the heart : but this must be a very uncommon thing. Scrofulous disease is not at all unfrequent in bone, especially in the bodies of the vertebræ, and in the spongy extremities of the long bones.

It is very seldom indeed that scrofulous tubercles occur in one organ only. Almost always they are met with in at least two, and frequently in all the parts at once which are liable to be infested by them. Sometimes the lungs al ne are affected : but generally both the lungs and the intestines are occupied by the disease. It has been affirmed, by a great living pathologist, M. Louis, that if you find tubercles in any other organ, you are sure to find them also, and in greater number, and arther advanced, in the lungs. But this, though true as a general rule, is not without exceptions. I have seen the peritoneum crowded with myriads of these tubercles, when the most careful examination could not detect a single one in the lungs. And similar examples have fallen under Dr. Carswell's observation.

The question has been much, and eagerly discussed, whether the deposition of tubercular matter be not, what I should call, an *rent* of inflammation. Some persons have strenuously argued that the curd-like substance is nothing more than a particular kind of lymph, and that it is never poured out except as a consequence of inflammation ; and they cite cases of persons who always had enjoyed good health, until inflammation was accidentally excited in their lungs ; immediately after which the well-known signs of phthisis began to display themselves ; and after death, the lungs were found full of tubercles. But they forget to take into the account another fact, equally well established, viz. that tubercles are found, in great abundance, in the lungs of persons who were never

known, in their lives, to have any functional disturbance of those organs ; and whose lungs present, after death, no other traces of having been inflamed. We even find tubercles in the lungs of unborn children. Not that this is conclusive ; for inflammation does sometimes attack the fœtus in utero, and leave permanent and unequivocal traces of its action.

Moreover, inflammation continually happens, in all the component textures of the lung, in the form of bronchitis, pneumonia, and pleurisy, without the subsequent development of tubercles. I admit that this fact, to be of weight, should be proved of persons who possess the scrofulous diathesis ; and I believe the proof might be found : but the search for it would require much carefulness and candour

In my own opinion, there is not the shadow of evidence to shew that the deposit of tubercular matter is always and necessarily preceded by inflammation. Yet an undoubted and most important *connexion* obtains between the occurrence of inflammation and the occurrence of tubercles. Tubercles will cause inflammation, and inflammation will determine the development of tubercles. The enlarging tubercles excite inflammation in the surrounding textures by the pressure they exert upon them ; and probably in other ways ; by mechanically interfering with the healthy circulation of the blood, for example : and the inflammation lit up is usually of the scrofulous kind ; it is slow, and partial, and easily *quieted* by treatment, though scarcely to be *cured*. On the other hand, there are numerous facts to prove that, in a person having the scrofulous diathesis, the occurrence of inflammation within the chest may rouse that previously dormant tendency into action, and become the exciting cause of the secretion of tubercular matter from the blood. The cases in which other parts of the lung than the apex are found exclusively occupied with tubercles, are also cases in which, apparently, the same parts had been the seat of inflammatory action : of which we sometimes see other traces in adhesions of the neighbouring pleura.

The connexion between tubercles and inflammation is shewn also by their occurrence in the substance of false membranes. And the same phænomenon marks the fact that they are something distinct and different from coagulable lymph.

You must not suppose, from any thing I have said, that persons of the scrofulous habit are not susceptible of *common* inflammation : we know that they are, by the readiness with which slight injuries often heal in such persons : but there is always much reason to apprehend that inflammation occurring in them will take on the scrofulous form ; become chronic, if it was not so at

first, suppurate tardily, and produce that unhealthy kind of puriform secretion which is characteristic of strumous disease.

Another question relating to tubercular diseases is, whether they are *contagious*: capable, *i. e.* of being communicated from one individual to another. The general belief, in this country, is that they are not. Indeed their very dependence upon a peculiar diathesis would seem to disprove the supposition. Yet some practitioners, even here, have, I know, misgivings on the subject: and in some parts of the continent, in Italy particularly, consumptive patients are shunned, from the persuasion that their complaint is infectious. I shall revive this question when I speak of phthisis hereafter.

Strumous diathesis.— I have stated, that scrofulous disease appears almost exclusively, in certain *classes* of persons, of whom, therefore, we say, that they have the scrofulous diathesis.

It is both interesting and useful to be able to distinguish those in whom the scrofulous habit of body, or the predisposition to strumous disease, exists.

Now there are certain physical and moral characters which teach us to apprehend the existence of a tendency to scrofulous disease, even when there has not, hitherto, been any local manifestation of such disease.

Again, we infer the scrofulous diathesis, in many persons, from knowing that scrofulous disease has existed among their progenitors.

On these two points I have a few observations to make: and first, on what may be considered the external marks of a scrofulous constitution.

The persons, in whom scrofulous disease is *most* apt to declare itself, are marked, during childhood, by pale and pasty complexions, large heads, narrow chests, protuberant bellies, soft and flabby muscles, and a languid and feeble circulation. They present many of the features belonging to that pattern of body which is denominated the leucophlegmatic. But the strumous disposition very often indeed accompanies a variety of the sanguine temperament also; and is indicated by light or red hair, grey or blue eyes with large and sluggish pupils and long silky lashes, a fair transparent brilliancy of skin, and rosy checks. This red colour, which is well defined in general, is easily changed, however, by cold, to purple or livid ; the skin is thin and readily irritated ; the sclerotic has often a peculiar pearly lustre ; and the extremities are subject to chilblains. Such children are, many of them, extremely clever and ready of apprehension, of eager tempers, and warm affections, lively, ardent, imaginative, and susceptible. This

precocity of mind and intellect, while it delights the fondness of the parent, awakens the fears of the more far-seeing physician.

But the disposition to scrofula is by no means confined to persons of the serous or of the sanguine temperament. It is frequent, though less common, in what has been called the melancholic or bilious temperament ; in persons of dark muddy complexion, and harsh skin ; in whom the mental and bodily energies are more sluggish and dull. And it is remarked that in persons of this cast, scrofula, when it does occur, is even more than usually obstinate and untractable.

Scrofula does often indeed appear in persons who exhibit none of those signs of a strumous disposition which I have been enumerating : but it is *more likely* to appear, cæteris paribus, where those signs *are* observed.

There are several alleged marks of a scrofulous *diathesis*, which are, in fact, instances of scrofulous *disease*. Such, for example, is that chronic lippitudo, which so frequently disfigures strumous children, rendering them what is called blear-eyed : and chronic inflammation of the conjunctiva, lasting long, without much redness, or heat, and with extreme impatience of light, and a tendency to form little pustules near the edge of the cornea. The tumid and chopped upper lips ; the redness and swelling of the columna nasi, and lower parts of the nostrils, so common in children, especially during winter, are early fruits of the strumous taint. Certain maladies of the joints, what are popularly called white swellings, are instances of scrofulous disease. So may perhaps rickets be considered : at any rate, rickety children are very often affected with scrofula also. Moist eruptions behind the ears ; chronic enlargement of the glands of the neck ; that slow, eating, ulceration of the nares, termed lupus; may all be included within the class of strumous disorders.

When any one of these scrofulous affections has once shewn itself in any person, we know, by that circumstance, that he possesses the strumous constitution ; and we look for the recurrence of his complaint in the same part, or in both parts.

In a former lecture I mentioned scrofula as one of those complaints the hereditary tendency to which is indisputable. The scrofulous *diathesis* is hereditary: and sometimes scrofulous *disease* is so too. I have seen lungs, taken from the body of a fœtus, stuffed with tubercles. There are some fine examples of this in Mr. Langstaff's museum, in the city. We have, therefore, in respect to scrofula, the rare conjunction of congenital disease, and hereditary disposition. I need not repeat here the remarks I made

before, respecting hereditary diseases in general. No one, of the least observation, can doubt that the disposition to consumption is very often transmitted from parent to child. We see whole families swept away by its ravages. Like other hereditary tendencies, it may skip over one or two generations, and reappear in the next, just as family-likenesses are known to do. There are other families in which you can trace no such predisposition : but such families are perhaps few. A little leaven is sufficient, sometimes, effectually to taint a whole pedigree. The tendency, however, exists in very various degrees. It may be so strong that no care, no favourable combination of circumstances, will prevent its local manifestation : and it may be so faint that it would never break out into actual mischief if the exciting causes of scrofulous disease could be warded off. It is important, therefore, to know what these exciting causes are.

"They may all be ranked together (to use the language of Dr. Alison) as causes of *debility*, acting permanently, or habitually for a length of time, although not so powerfully as to produce sudden or violent effects."

The circumstances to which, acting separately or in combination, we most confidently ascribe the power of developing scrofula, are insufficient nutriment, exposure to wet and cold, impurity of the atmosphere, a want of natural exercise, and mental disquietude. To estimate the separate effect of each of these causes may be difficult ; but their combined influence is unquestionable.

There can be no doubt that improper diet, or rather imperfect nourishment, is one main exciting cause of scrofulous disease. Yet it is not an easy thing to obtain evidence of this, which shall be entirely free from fallacy. The disease occurs very often among the poor ; but then it very often occurs also in the families of the rich. There is one fact which has always struck me as very instructive and convincing on this point. Infants at the breast, having good milk and plenty of it, seldom show any signs of scrofulous disorder : whereas, as soon as they are weaned, they become subject to various complaints of a strumous kind. When an unweaned child is brought to us with ophthalmia, we expect almost always to discover inflammation of the common and acute kind ; the purulent eye. In nine children out of ten who come after weaning, we look for and find some form of scrofulous inflammation, such as pustular ophthalmia.

The greater prevalence of scrofulous disease among the poor may be ascribed, in great measure, to their frequent exposure to wet and cold. Scrofula seldom breaks out in the mild and dry weather of summer. The influence of climate in fostering or repressing the disease is notorious. There is no climate in which it flourishes more than in our own. Consumption is called, in some parts of the continent, the English disease. Persons who migrate from this country to warmer and more equable climates, seldom become scrofulous ; nay, it very often happens that the incipient indications of strumous disease are completely arrested or quieted by the change. Phthisical patients, much troubled by symptoms here, are sometimes so thoroughly freed from them soon after their arrival at Madeira, as to be deceived into the belief that their case had been mistaken. They think themselves well. A return to this country undeceives them. The native inhabitants of hot climates are by no means, however, exempt from struma, in any of its forms. When they come to this country they are more subject to scrofula than we are ourselves. And the same effect of climate is very distinctly visible in the lower animals. The physicians in ordinary to the inmates of the Zoological Gardens will tell you that the beasts and birds that are brought hither from warm latitudes perish in great numbers from scrofulous diseases. John Hunter observed this long ago in respect to monkeys.

Of the debilitating influence of impure air I spoke in a previous lecture. That it promotes the evolution of scrofulous disorders we have proof, on a large scale, in the great mortality produced by such disorders among the lower classes in large cities as compared with agricultural districts. The per centage of deaths from consumption, hydrocephalus, and various other diseases that spring from a strumous habit, is much greater in London than in the country. Even in individual cases this influence is too manifest to be overlooked or mistaken. It is impossible to question the beneficial effect, upon children afflicted with scrofula, of a removal from London to the sea-coast.

I said, when I first began to speak to you of inflammation, that it was the only disease which we are able to excite at pleasure : that we could cause inflammation in various ways whenever we desired to do so ; but that to make a cancer or a tubercle was beyond our power. Now in strictness of language, and in the practical meaning of these words, this assertion is quite true. But it is not so exact if we extend it to all the *predisposing* causes of disease. We are able to bring about the formation of tubercles, in the lower animals at least, by so arranging the external influences as to concentrate their prejudicial effects. By shutting rabbits up in a cold, damp, dark, and narrow place—and feeding them on food not natural or suited to them— we can produce or evolve in them tubercular disease. Of course no experiment of that

kind can be purposely made upon a healthy man ; but accidental opportunities arise of witnessing an approach to a similar trial of the human species : instances are recorded of persons, previously well, (but having probably the strumous diathesis) becoming affected with scrofula after being confined in the dungeons of a prison, and there scantily fed.

Something of this kind I have, very recently, had the opportunity of seeing.

A number of male prisoners, chiefly young men, became affected with glandular swellings of the neck, after incarceration for some length of time in the Penitentiary at Milbank. The circumstances of their health led to a relaxation of their punishment. Instead of being kept in solitary confinement, in a coldish cell, and on the prison diet, they were permitted to work, for several hours daily, in each others' company, in the garden of the establishment. Some porter was at the same time given them, and their allowance of meat was increased. The improvement in their condition was rapid and striking. Here we have the disorder germinating under one state of external circumstances, and checked immediately under the opposite state.

If you consider the way of life of the children of the poorer classes in this metropolis, and in the larger manufacturing towns, you will find that they are much exposed (though in a less degree) to the same injurious influences, the combination of which appears to generate tubercles in the rabbit. They live, for the most part, in an atmosphere made stagnant by narrow streets ; and in small, crowded, ill-ventilated, and dark rooms in those narrow streets : the stagnant atmosphere is contaminated in a thousand ways ; they are very insufficiently protected from transitions of temperature, against cold and wet, by their clothing ; they are commonly ill fed—their diet being frequently scanty, and generally of a kind quite unsuited to their growing years. We need not be surprised therefore at the ravages which scrofula, in its manifold shapes, makes among the children of the poor in large and populous towns. If ever scrofula be generated, in this climate, independantly of any hereditary strumous taint in the constitution, it is in them. But in most cases I believe it is the latent disposition that is called into action. Moderate exercise, in pure air, and in the open daylight, with suitable nourishment, sufficient clothing, and attention to the state of the bowels : these circumstances comprise nearly all that we can do for preventing the development of struma : and from each of them many of these poor children are habitually debarred.

Erysipelas—Diagnosis of Abdominal Tumors—Cases of Encysted Dropsy and Abdominal Tumor.

ERYSIPELAS.

Erysipelas is a very common disease in our hospital at particular seasons, and you must have frequently witnessed its symptoms and progress. In the following observations we mean to confine ourselves chiefly to the treatment, as it involves a peculiarity not generally adopted, and which was first noticed by Mr. Higginbottom. It is agreeable to our experience, and we believe generally admitted by accurate observers, that the violence of the constitutional symptoms is, in the majority of cases, proportionate to the extent of the erysipelatous inflammation ; and thus a partial affection of an extremity, or of the face, is generally attended with little urgency in the general symptoms ; whereas, when the whole head and face become affected, or a whole limb or the trunk of the body, it often becomes an affection attended with much danger. If this be admitted, it then becomes quite obvious that an insulation of the disease, or a limitation of its progress, is a matter of the most essential importance. That this is practicable we have no hesitation in stating, and that it will succeed in the majority of cases we are also satisfied, provided it be carefully performed, and with attention to the rules which we shall presently explain. Nitrate of silver is the agent by which this may be accomplished ; and the following principles must be attended to, to insure success :— 1st. It must be applied to a sound portion of the integuments, viz. to a part where there is neither redness nor œdema, but as near the affected skin as possible, so as to avoid this. We have seen failures repeatedly from want of attention to this rule ; for, on the one hand, if your caustic line be too far distant from the part affected, the vesicating effect of the nitrate of silver may have completely subsided before the erysipelatous inflammation reaches that portion of the skin to which it was applied ; and on the other, if too near, the erysipelas may be beyond the line at the time of its application, even although there be no redness present. We have generally observed in this disease, that beyond what is commonly considered the red line of separation between the healthy and diseased skin, there is about an inch or more of œdematous integuments, which are often somewhat tender to the touch, and where, we have no doubt, the disease

also exists. 2d. The erysipelatous surface must be completely encircled by the caustic line; for if even a minute chink be unvesicated, the inflammation will pass through it, and spread beyond the boundary.

The practical rules to be attended to are the following :—Take a pretty large hair-brush, and moisten thoroughly with water the part that has been selected, to the breadth of about an inch ; then rub a cylinder of lunar caustic very freely over this moistened portion of the skin. Distinct vesication over the whole surface, to which the caustic has been applied, should be produced ; for if this does not follow, the disease may extend beyond the line.

And this is, perhaps, the reason why a saturated solution (consisting of equal parts of lunar caustic and water) is not so certain as the solid caustic. How then does the nitrate of silver act, in thus insulating the erysipelatous inflammation ? The following theory may explain its peculiar operation :—The inflammation appears to travel in its progress superficially along the skin, and it may even be detected by a very slight degree of œdematous tenderness, about an inch or so beyond the red line ; but there appears to be no affection of the cellular texture in this situation. Now the vesication produced by the action of the nitrate of silver may have excited an action which is incompatible with the progress of the erysipelas in that direction. This view is corroborated by the fact that if the caustic line be formed at too great a distance from the diseased surface, and if the latter be slow in its progress, then the line is less certain in its preventive power ; for the vesication caused by lunar caustic heals very rapidly, and perhaps more so than blistering produced by any other agent.

We have thus stated our opinion pretty strongly as to the efficacy of this mode of treatment, believing, as we do, that it is capable, in the majority of instances, of checking the extension of the disease, when applied according to the principles already explained ; and also that, in our experience, the fatality of this affection, from its extension over the body being frequently prevented, has been less than we experienced under the usual therapeutic means.

At the same time, we are willing to admit that we have met with some instances where the erysipelas has travelled beyond the properly vesicated line ; and also a few, where one or two smaller insulations were required, in cases where it only passed at a particular point of a limb or trunk of the body.

It must also be acknowledged, that erysipelas is often confined to particular parts of the integuments, independent of the operation of any particular treatment, such as to the head and neck, a portion of an extremity, &c. ; but if we find a regularly progressive inflammation checked at points, where it rarely stops spontaneously, such as at the eye-brows, the chin, or the nose, whether it be ascending, descending, or crossing laterally, more particularly if it come into close proximity with the caustic line, it is fair to conclude that the latter had proved a barrier to its further extension.

In typhus fever erysipelas is very frequent during the convalescent stage, and generally attacks the face or head ; but, in our experience, it is not quite so apt to spread to the trunk as in the idiopathic affection ; at the same time it does so very often. During the time that we attended the Fever Hospital, this disease was exceedingly common ; and, with the exception of two or three cases, chiefly confined to those where the insulation was either not performed sufficiently early, or, with strict attention to the rules mentioned, the affection never extended to the trunk, and in many instances it was confined to the face, nose, cheek, &c.

The state of the previously-affected parts in erysipelas does not seem to be much influenced by the checking of its progress, for resolution or suppuration occurs in a similar way as when it is allowed to spread ; with the exception, perhaps, of the first-mentioned process, which appears to be more rapid in the immediate vicinity of the caustic ring. The counter-irritation excited by the nitrate of silver seems also to be beneficial in local affections which sometimes accompany this disease, viz. delirium, diseases of the chest and windpipe ; and also in preventing suppuration in the neighbourhood of the vesication. Besides the uses of lunar caustic in frequently checking the progress of erysipelas, it is one of the most powerful agents, when applied in solution to the inflamed skin, particularly where the cellular tissue is not much implicated, in reducing the redness, pain, and swelling ; for on the day following its application the skin is generally less tense and red, and is often somewhat shrivelled. If, however, there be effusion of serum or pus into the cellular tissue, incisions are generally necessary. The strength of solution we employ varies from ten to twenty grains of this salt to one ounce of water, applied twice a day with a hair pencil. In the general treatment, the tonic plan has generally succeeded best, particularly in hospital practice, where many of the patients have broken-down constitutions by intemperance and other causes. In stout and vigorous patients the emeto-cathartic mixture may sometimes be employed with advantage ; but it ought not to be pushed too far, and laxatives or laxative enemata should be substituted for it, in a large majority of cases, for we have never seen reason to believe that it has any direct power in

checking the extension of the inflammatory action. We shall now state, very shortly, the history of a few cases of erysipelas, in as far as is necessary to illustrate the operation of the nitrate of silver in checking its progress.

Wm. Gibbie, æt. 50, was admitted for paralysis on the 23d Nov. 1839, for which a seton was inserted in the nape of the neck. About the 2d Dec. some erysipelatous inflammation appeared around the wound, which spread downwards and upwards. No attempt was made to check it at any point except in the arms. It had passed the acromion a few inches, and was advancing pretty rapidly ; a caustic ring was formed on both arms, near the insertion of the deltoid, and the following is the report of the result :—" Erysipelas did not spread beyond the caustic rings, although it reached them at every point. Since the abatement of the erysipelas, the paralysis has been much less, and the patient can now walk with tolerable freedom."

Jane Melville, æt. 19, admitted 1st Feb. 1840, for erysipelas of the left leg, which was swollen, red, and partially covered with vesications from the knee downwards. A caustic ring was formed immediately above the knee, beyond which the inflammation did not spread. Extensive suppuration followed, in this case, which, along with the severe bronchitis under which she laboured, protracted her recovery for a considerable time.

Mary M'Lean, æt. 29, was admitted for nodes upon the head, on the 14th Jan. 1840. She was blistered on the nape of the neck on the 30th, and the resulting sore was attacked with erysipelas in a few days thereafter. It spread down the back, and upwards, along the head, to the face. No attempt was made to check its progress along the back, but a caustic line was formed from the tip of the right ear, over the chin, to the same part of the left ear, beyond which the inflammation did not spread. She recovered in a short time, and her pains were gone.

Mrs. Kinneburgh, æt. 62, was admited on the 10th Feb. 1840, for erysipelas of the foot and leg, which extended posteriorly to the middle of the thigh. A caustic ring was formed as near as possible to the affected parts, and there was no extension of the disease beyond that point. She recovered rapidly under wine and tonics, although a slough formed on the back of the foot.

Isabella Harvey, æt. 40, was admitted on 11th Feb. with erysipelas of the forehead and face, which was spreading pretty rapidly down the neck, both anteriorly and posteriorly, on the 14th. A caustic ring was formed below the erysipelatous margin, beyond which the disease did not extend.

She was dismissed, cured, on the 17th, having had no other treatment except a laxative, small doses of the diaphoretic mixture, and the solution of the nitrate of silver externally.

Daniel Culcreuch, æt. 40, was admitted on the 18th Jan. 1840, for acute anasarca and bronchitic pneumonia. On the 25th, erysipelas appeared around the right eye, which spread over the face, and was descending the neck. A caustic ring was formed around the neck, beyond which the inflammation did not extend. He was dismissed, cured, on the 6th February.

John Shaw, æt. 25, was admitted on the 30th Dec. with cynanche maligna, accompanied with laryngitis. On the 6th Jan. some erysipelatous inflammation appeared on the nose, which spread upwards to the forehead. A caustic ring was formed about the inflamed parts, beyond which the disease did not spread. He required a large quantity of wine to support his strength, but was ultimately discharged cured.

James Docherty, æt. 18, was admitted on the 27th March, 1840, for enormous anasarca of the whole body, arising from hypertrophy and valvular disease of the heart. He was affected with erysipelas of the leg on the 1st April, which spread rapidly up the thigh. A caustic ring was formed about the inflamed parts, pretty near the groin, which limited the extension of the disease upwards. One or two small abscesses formed in the leg, but the general swelling and inflammation diminished very rapidly after the application of the caustic. There was another fact connected with the patient's history which is worthy of being recorded, viz. the rapid diminution of the anasarcous swelling and the great increase of urine about the time that the erysipelas began to decline. The urine, for about a week, averaged from seven to nine pounds daily ; and after his anasarca was completely gone, the increased impulse of the heart, and the strong rasping bruit, which formerly existed, were barely distinguishable.

ABDOMINAL TUMORS.

IT is frequently very difficult to determine the precise nature of abdominal tumors, and post-mortem examinations occasionally demonstrate the fallacy of our diagnosis. At the same time, by a careful exploration, and accurate analysis of the general symptoms, a pretty correct opinion may often be formed. It would be inconsistent with the nature of a clinical lecture to describe the different methods of exploring the abdomen in the various diseases of this cavity ; we shall therefore confine ourselves to three, of which we have examples ; viz. the detection of fluid in the cavity of the peritoneum, or in cysts, the detection of tumors, and the

mode of ascertaining whether the swelling or tumor be under or above the abdominal muscles. It is in general easy to detect fluid in the cavity of the peritoneum, when the quantity is pretty considerable, but when it is small it is sometimes more difficult of discovery. Percussing the abdomen with the finger, while the hand is placed on the opposite side, is, generally speaking, conclusive of the existence of fluid, when a peculiar vibratory fluctuating motion is felt. When there is much fluid present, and consequently great distension, this motion is felt in any position of the patient, but if it be small in quantity it is necessary to place the patient on his back, or, if he be strong enough, in the erect posture, which causes the fluid to gravitate to the lower part of the abdomen. Mediate percussion with the pleximeter is also of considerable value in such cases, for when fluid is accumulated in the abdomen a dull sound is produced in the situation where it is lodged. In doubtful cases the diagnosis is rendered more certain by changing the position of the patient. Thus, if, in the horizontal position, after the bowels and bladder had been freely emptied, the percussion all over the abdomen was clear, while in the erect posture it was found dull inferiorly, the conclusion would be pretty certain that the cause of the dull percussion in the latter case was fluid.

In encysted dropsy, or tumors of the abdomen, there is always, at their commencement, a distinct swelling, which is generally capable of being defined by the hands, and sometimes by ocular inspection, and its shape is different from an ascitic swelling. In percussing a tumor of this kind the sound is always dull, and the fluid or solid not being able to change its place, as in general effusion, into the peritoneal cavity, its sphere is more fixed, or limited to a particular port of the abdomen. Sometimes, however, the cyst or tumor is loose, and may change its place from one part of the abdomen to another; but, in this case, it does not take the level of gravitation, or descend to the lowest point of the abdomen, as in ascites. In some cases also an obscurity may arise, if percussion alone be trusted to; for a portion of intestine may cover the tumor, and from this a clear sound may be elicited. This may in general be avoided by depressing the pleximeter to the level of the tumor. The stethoscope may also be used as an auxiliary in the diagnosis. When this instrument is applied to the abdomen in its healthy state, the motion of flatus is frequently heard in the regions where the intestines are situated. This movement is sometimes interrupted, but by causing the patient to cough it generally recommences. When the abdomen is much distended with serum, it is not heard in

those situations where the stratum covering the intestines is very deep; but when it is less so, the sound is heard as if deep seated. Again, if the stethoscope be applied to a tumor which springs from the posterior walls of the abdomen, and if this instrument be firmly depressed upon it, no sound whatever will pass through the stethoscope to the ear. We have verified these statements in a number of cases: at the same time we would caution you only to use this plan as an auxiliary means ; for it is quite possible that it might be indurated intestine, even although no flatus was discovered passing through it ; but if, on the other hand, borborygmi are heard in an abdominal tumor, the evidence of its intimate connexion with the intestines would be more positive.*

It is sometimes difficult to ascertain whether a tumor be situated above or below the abdominal muscle, more particularly in fat persons. When an abscess, or chronic induration, is seated in the interstices of the abdominal parietes, percussion is of considerable value ; for unless it be very large a tolerably clear sound will be elicited if sufficient force be employed ; whereas, if its origin be within the abdomen, the sound is, in every case, perfectly dull. A careful examination with the hands must also be made ; for in the majority of cases, by insinuating the fingers into the abdomen pretty deeply, on each side of the tumor, its deep seat or superficial situation may be detected. If the affection be seated in the cellular texture, you may sometimes be able to elevate it from the abdominal muscles, and ascertain its thickness. This method may be employed to detect depositions of fat or serum in the cellular texture, and phlegmonous inflammation existing there, before it has extended much. The history of the case is also of importance, particularly regarding abscesses ; for those which are internal are generally more slow in their progress than those which are external.

CASE OF ENCYSTED DROPSY.

Mary M'Nicol, æt. 46, unmarried, having had no children, was admitted on the 24th of March, 1840, with the following symptoms. Abdomen is very much swollen,

* As it is not worth while to make a separate communication on the subject, it may be here stated that we have lately, in two or three cases, ascertained the value of the stethoscope when applied to the penis, in determining the existence of calculus during the process of sounding ; and the superiority of this situation to the pubes, the place generally selected. The principle of its superiority is easily explained ; for when the stethoscope is applied to the pubes during the percussion of the calculus, the sound is communicated to the ear through the medium of the soft parts and bones of the pelvis ; whereas, when the instrument is applied over the penis, the sound is communicated by a metal, which is a much better conductor.

measuring forty inches around umbilicus ; not very tense, and it fluctuates very distinctly. The right side, half way to umbilicus, projects somewhat more than other parts of abdomen, and feels more distended. Is much troubled with cardialgia, pyrosis, and acid vomitings; complains of pain in epigastrium and left hypochondrium, occasionally shooting to right side. Appetite tolerable ; bowels regular ; tongue white ; skin cool, very harsh and dry, and no precipitate is thrown down from it by heat or nitric acid : no cough : percussion and sounds of chest good. States that she first observed the swelling six years ago, and that it has since gradually increased, and has not been removed at any time by treatment. Menstruation is regular.

This patient was treated with diuretic powders, composed of squills, digitalis, supertartrate and nitrate of potass, along with pills of calomel and opium, to the extent of salivation, without benefit. The following report was taken on the 14th of April :— Percussion of abdomen completely dull, except at left side inferiorly, which is clear, and at the junction of the clear and dull portions there is a distinct line of indentation. Some salivation : pulse 68, soft, weak ; tongue red and dry ; bowels pretty open. At this date the pills were omitted, and paracentesis abdominis was performed, and on examination of abdomen afterwards, a thickened or hardened ridge or margin was discovered surrounding its cavity, particularly on right and left sides. Twenty-one pounds and a half of serum were evacuated, which was colourless, slightly opalescent, and of sp. gr. 1008. It had a faint saline taste, was almost neutral, and a scanty precipitate was thrown down by the addition of nitric acid, indicating a little albumen. Nitrate of silver caused a copious precipitate, but none was produced in it by the addition of chloride of barium. Sulphuric acid occasioned an effervescence, and the derangement of a gas, which produced with ammonia a white vapour. An excess of tartaric acid caused no deposit. 500 grains, when evaporated, left a residue of 7·5 grains of a salt, which seemed to be almost entirely chloride of sodium, having the taste and several of the other qualities of this substance.

After the operation of tapping, the diuretic powders were continued for about a fortnight, but the urine being still below the natural quantity, viz. about two pounds and a half, they were omitted, and a solution of the acetate of potass employed, according to the following formula :—

℞. Acet. Potass. ʒj. ; Aquæ ʒviij. Solve. Cap. ʒi. solutionis ter in dies.

She had also a few ounces of wine daily to support her strength. Under this treatment the urine increased to about three pounds and a half daily : her general health was improved, and she left the hospital about the middle of May, being about five weeks after the operation, without any appearance of the regeneration of the fluid in the abdomen, although there is every probability that it will return.

REMARKS.—Upon what grounds, then, is this case classified as one of encysted dropsy, for in several of its general characters it resembled ascites. They may be reduced to the following :—1st, The irregular shape of the swelling, and the tympanitic sound which was elicited from the left inferior side of the abdomen. 2d, The thickened margin which was discovered surrounding the abdomen after the fluid was evacuated, and the appearance of the serum, which differed from the ordinary ascites in several of its qualties. 3rd, The slow progress of the disease. The irregular shape of the tumor was quite distinct in the horizontal posture, although, from the considerable size of the swelling, and prominence of the abdomen, it might readily have been mistaken for ascites on a superficial examination. The tympanitic or clear sound of the abdomen on the left side cannot be accounted for on the supposition that it was an ascitic accumulation, for in this disease the gravitation of the fluid during the horizontal position of the patient necessarily renders the percussion dull in the inferior and lateral regions. This view is also supported by the existence of a thickened margin, especially at the lateral parts of the abdomen, which may readily be explained by taking into account the collapse which would take place in the sac after the evacuation of the fluid, and the facilities which were then offered for ascertaining the thickness of its parietes. The serous fluid evacuated was also different from that which generally exists in ascites, in being of less specific gravity, colourless, in containing so little albumen, and such a large proportion of common salt. We would not, however, lay much stress on the chemical constitution of the fluid, for we are not in possession of a sufficiently extended series of facts, connected with the chemical constitution of dropsical fluids, to warrant us in drawing very certain conclusions from them ; at the same time, it is right to admit, that this species of evidence, although not so certain at present as it is likely to become at some future time, is a corroboration of the other symptoms. The slow progress of the disease is also another point in which it differs from ascites, for the latter is much more rapid in its progress, and is accompanied with a more serious deterioration of the general health, than what occurred in our patient during the six years that she laboured under the affection.

Cases of this kind are by no means common, and are even more rarely met with than ovarian dropsy ; but several of this description have been detailed by authors ; and Mr. Coulson relates a case where the cyst adhered to the abdominal parietes and several of the viscera.

ABDOMINAL TUMOR.

Mary Adam, æt. 24, married, having had one child about three years ago, was admitted on the 8th of March, 1840, having the following symptoms :—Occupying left lumbar region of abdomen there is a roundish tumor, which projects considerably, is about the size of a large melon, has a firm elastic feel, and is the seat of considerable and constant pain, which is very acute on the slightest touch. No stool for three days, and bowels are habitually constipated ; tongue whitish ; appetite pretty good. Affection commenced about two months ago, and ascribes the cause of it to constipation. States that it has twice been of its present size, and was diminished by purgatives. Menstruation regular ; uterus normal.

Abstrah. ℥x. Sang. part. dolent. c. c. Cap. Ol. Ricin. ℥i. c. Submur. Hyd. gr. v.

March 16th.—Swelling increased, and indistinctly fluctuates ; has frequent perspirations ; bowels regular.

19th.—Tumor still increasing, and there is some throbbing pain felt in it ; parietes thinner ; pulse 84, soft ; bowels rather constipated.

App. Cataplas. emoll.

23rd.—Yesterday about six ounces of thin, brownish, fœtid pus, were evacuated from tumor by grooved needle and cupping-glass. This morning a small ulcerated opening formed near wound made by grooved needle, through which 19 ounces of similar pus were discharged. Pulse 68, moderate ; tongue clean, moist ; opening closed by strap and bandage.

Hab. Cerevis. Fort. lb. ii. indies.

25th.—About 12 ounces of more consistent and less fœtid pus were discharged to-day from spontaneous opening ; less swelling : feels stronger : pulse 80, soft.

April 2d.—This morning a considerable quantity of pus was spontaneously evacuated from opening : pulse 72, moderate ; no sweating ; tongue white.

April 5th.—Since last report two or three ounces of more healthy pus have been discharged from opening every second day, and there is now no fluctuation, but surrounding swelling is very firm : pulse 84, moderate ; tongue clean ; appetite good.

13th.—Some clean serum has been discharged from opening for the last two or three days, and probe passes into it perpendicularly to the depth of one inch and a half.

There is now no fluctuation ; but a firm slightly moveable tumor exists, fully larger than the first, but not painful when pressed : pulse 68, moderate ; tongue pretty clean ; some nocturnal sweatings ; bowels regular.

This patient was dismissed about the beginning of May, with the ulcerated opening cicatrized, but the hard tumor still remained, but was not painful. Her strength and general health were greatly improved.

REMARKS.—This disease seems to have been in a somewhat indolent state before the patient's admission into the house ; for, according to her statements, it had existed for two months, and had been diminished once or twice by purgatives. After her admission, however, it increased considerably ; for at that time it was about the size of a large melon, with little prominency, whereas now the part that projects is about the size of the fist, and on pressing the fingers on each side of the tumor, down towards its base, which appears to be deep-seated, it feels nearly as large as a child's head. It seems perfectly encysted, and unconnected with the general cavity of the peritoneum, although there can be little doubt of its being situated under the abdominal muscles. No murmur of flatus has ever been detected in it ; we are therefore inclined to think that it is not immediately connected with intestinal disease, and, with the exception of constipation, there seems to be nothing abnormal in the state of the bowels. In all probability it has its origin in the cellular texture lining the left lumbar region ; for it has little mobility ; whereas, did it arise from the omentum, mesentery, or other moveable organ in the abdomen, it would be much less fixed in its situation. It has, therefore, all the characters of a chronic abscess, viz., first the chronic induration, then the gradual softening, prominency, fluctuation, slight throbbing pain, perspirations, &c. The nature of this case, after a careful analysis of the symptoms, was, therefore, pretty clear, but the mode of treatment also required some consideration. If our opinion was correct, no immediate risk to any of the abdominal viscera would be the result of opening the abscess ; but it was equally obvious that a free incision into it, by admitting the air into its cavity, might excite high irritative fever, which might of itself be highly dangerous. We therefore resolved to adopt a practice which we have repeatedly had recourse to in opening chronic abscesses situated in other parts, and also in discharging puriform matter from the joints, viz., puncturing with a grooved needle, and the application of a cupping-glass. This plan was only tried once, with our patient, in consequence of the parietes of the abscess having ulcerated. In order, however, to approximate the treatment as nearly as possible to the plan we intended,

the opening was carefully secured by adhesive straps and bandage, as soon as the matter was evacuated. Her general treatment consisted of occasional purgatives, wine, and light nourishing diet, to support the strength. The prognosis, in this case, of the ultimate result is certainly unfavourable ; for though the immediate danger arising from the suppurative inflammation has been got over, a hard indolent tumor still remains, which very likely may suppurate again if any new irritation be excited in it by constipation or other causes, or even without any assignable reason : at the same time it is possible, from her youth, that it may be absorbed, provided she carefully attends to the improvement of her general health.

CONGENITAL OPACITY OF THE CORNEA.

By Mr. S. Crompton, of Manchester.

Two children of the same parents born with opaque corneæ.—The appearance of the eyes at birth, and now.—The testimony. Three children in another family, supposed to have been born with opaque corneæ. These cases described by Mr. Farar in 1790. Mr. Middlemore, surgeon at Birmingham, disbelieves them. An examination of Mr. Middlemore's judgment.

To the Editor of the Medical Gazette.

Sir,

There are two brothers in Manchester who are commonly supposed to have been born with opaque corneæ. The elder boy is eighteen years old ; the younger three ; and they are the second and tenth of a family of ten children of the same parents : the eyes of the rest being perfect[*].

The right eyes of both brothers are staphylomatous ; the staphyloma being much more prominent in the eldest boy.

Their left eyes agree in the following particulars :—They are very small, and soft to the touch ; the line of union of the sclerotica and cornea is irregular, and less distinct than is natural. The irides are blue, and very convex. The eyeballs are wanting in plumpness and rotundity, and look unfinished.

[*] Of the condition of the eyes of the first born child of these parents, nothing is known. The child died within a few hours of birth, and its eyes were not examined.
This is a drawing of the younger boy's left eye. You see that an opacity of the cornea keeps a part of the pupil out of sight ; and that, at the upper part, there is an irregularity in the outline of as much of it as is visible. But the elder boy has a regular pupil, and the whole of his cornea is quite transparent, saving a small portion of the lower part of it at its junction with the sclerotica, and I am not sure whether this opacity is not from an encroachment of the sclerotica at this point, and a result of the irregular line of union of the cornea and sclerotica, of which I have already spoken.

The elder boy can see well. I have endeavoured to ascertain the exact degree of vision which the younger possesses, but without success. When he is examining any object, he turns his eyeball inwards and his head to one side, probably in order to present as much as possible of the pupil towards it. Things which he can handle he puts very close to his eye.

So far I have attempted to describe the *present* appearances of the eyes of these two brothers ; and, in the next place, I shall lay before you the testimony upon which the supposition, that they were born blind of their right eyes, and with opaque corneæ of the left, is founded.

First, *the testimony of the mother.*— (Whom I have known seven or eight years, and can perfectly believe). She states that on the day after he was born, she discovered that the eyes of the elder of these two boys were "not right." She was led to examine them by observing, when he was asleep, a prominence of the upper eyelid of the *right* eye. On looking at this eyeball, she discovered that it was far from being as it ought to be. It projected at that time as it does now, but not so far. The front of the *left* eye was partly covered by a "pearl." This opacity grew thin first of all at the outer edge of the cornea : that portion of it, which was at the nasal margin of the cornea, being the last to gain its transparency. Her surgeon saw the

eyes on the same day, and told her that medicine would be of no use to them.

Since the birth of this boy, she has always commanded her nurse to look at the eyes of her other children immediately after birth, to see if they were perfect. The third child, the fourth, the fifth, the sixth, the seventh, the eighth, and the ninth, were all born with perfect eyes: the tenth was not.

Her tenth delivery was attended with danger, and her surgeon tarried awhile with her. Before he left the house, the nurse discovered that the child's eyes were not right. They were shown to him immediately, that is to say, not later than one hour after birth. He gave her the same opinion that she got respecting her eldest boy, viz. that medicine would do no good. Most positively, there was no running of matter from this boy's eyes ; there was no discharge whatever ; neither were the eyes bloodshot, nor were the eyelids swollen. As to the elder boy, she cannot speak confidently. She does not remember that matter ran from his eyes: it may have done. It is so long since he was born that she is afraid to trust to her recollection.

Second, Mr. Allen, late house-surgeon to St. Bartholomew's Hospital, who attended the lady upon the birth of the youngest of these two boys, has very kindly given me the following particulars:—He saw the eyes immediately after birth, and distinctly remembers that the child was born with opaque cornea. He met Mr. Barton in consultation upon the case, and he remembers that the imperfect development of the eyeballs was particularly remarked. The child had not purulent ophthalmia.

Third, Mr. Barton, the senior surgeon to the Manchester Eye Hospital, remembers meeting Mr. Allen in consultation upon the youngest of these two children. He considered the eyeballs to be imperfectly developed[*], and from the testimony, he felt assured that the opacity of the cornea was congenital.

Fourth, I saw the boy when he was about a month old. I had no doubt

that the disease was congenital. There was no redness of the conjunctiva, nor granular state of the eyelids. I thought the case so remarkable that I have frequently called upon the mother to see the changes that were taking place in the eyes. At that period I made most diligent inquiries respecting the previous existence of inflammation, and satisfied myself that none had existed since birth. The entire cornea of the left eye was densely opaque. The outer edge of it cleared first of all.

Fifth, Mr. Walker, assistant surgeon to the Manchester Eye Hospital, tells me that this is the case to which he alluded in the following quotation :—

Purulent Ophthalmia, even before birth. By John Walker, Esq., Manchester.— " You will probably agree with me in thinking that this disease may arise from a number of causes, one of which may be some such secretion as that alluded to, and another a peculiar congenital predisposition. This extraordinary case I will state a little in detail, since, as far as I know, there is no similar one on record, although probably others must have occasionally occurred. The child, when first brought under my notice, was six months old, and the mother, a very intelligent person, informed me that at the time of birth its eyes exhibited the same appearances as were now observable. The disease had run through its entire course previously to birth, for, according to her account, there was no puriform discharge, inflammation, or intolerance of light, noticed at any time subsequently. The cornea of one eye had completely sloughed, the eyeball had sunk, and of course not the slightest vision existed[*]. More than one-half of the cornea of the other eye was opaque; through the remaining transparent portion a part of the pupil

---

[*] Mr. Barton pointed out to me a case from Ripon, in Yorkshire, in which there was a like imperfect formation of the eyeballs. In this case the *cornea* was transparent, but the *lens* opaque. The eyes were particularly small, and it was said that the child was born with these appearances.

[*] I saw this child for the first time when he was about a month old ; Mr. Walker when he was six. I remember distinctly that the right eyeball was particularly small, and that none of the iris was visible in the left eye. Since that time the right eyeball has grown very considerably. It has not been a mere increase in size, but, as it were, an evolution of an eyeball. Changes are continually taking place in it. Although the cornea is staphylomatous, it appears that there is an effort to restore its transparency. Within the last month or two, something like a pupil has become visible. It was first observed by the mother, who very anxiously watches the changes in her boy's eyes. These circumstances countenance Mr. Barton's opinion that the eyeball had been developed, not in utero, but arrested in its growth.

could be discerned, and the iris and cornea appeared almost in contact. The transparency gradually extended, and more of the pupil became accessible to light; hence, though vision was very imperfect when I last saw the child, yet it appeared to be gradually improving." — Braithwaite's *Retrospect*, vol. i. p. 115, taken from the Lancet, Feb. 8, 1840, p. 713.

Mr. Walker mentions another case which he saw on the second or third day after birth. Both corneæ " were opaque throughout, and unusually large and prominent, so that very little of the sclerotica was discernible. The opacity was of a bluish white colour ; there was scarcely any irritation about either eye ; nothing like inflammation." He regarded it as a case of malformation, and he says that, at the second year, the corneæ were " perfectly healthy, transparent, and of normal size."

I think it would be difficult to obtain more conclusive evidence respecting any congenital disease of the eyes than that which I have collected respecting the younger of these boys. The evidence is not so clear concerning the elder boy ; but if the following cases be true, it would seem certain that several children in the same family *may* be born with opaque corneæ.

An account of a very uncommon Blindness in the Eyes of newly-born Children. By Mr. SAMUEL FARAR, Surgeon, at Deptford. Communicated by Mr. WATSON. Read March 2d, 1790 *.

" About nine years since, I was desired to see a child, who was about a month old, and apparently blind, having the cornea of both eyes opaque, so that not the least of the iris was to be seen.

" My opinion was, that nothing could be done in this case, and that the child would for ever be blind.

" About a month afterwards the parents informed me there was some alteration in the child's eyes, and requested I would examine them again. I then perceived the opacity to be so much lessened that I could faintly discern the iris. In two months more the child could perceive light, and from that period the sight progressively increased ; and before it was ten months old the recovery was complete.

" About three years after, another child was born of the same parents with exactly the same appearances. Having seen the progress of the first case, I concluded that in this the event would be nearly the same, and, indeed, so it happened in much about the same space of time.

" The manner in which the cornea acquired its transparency was, in these cases, remarkably curious : the external edge, first growing thin, soon after became clear and transparent ; and after this manner the whole surface of the cornea brightened up, the centre being the last spot that recovered its transparency.

" Two years ago the same persons had a third child born with the same appearances, except that the opaque part seemed thicker, and that a short round ligament, about three-eighths of an inch long, and of the thickness of a probe, arose from the inner part of the upper eyelid, was attached to the inferior edge of the cornea, and, when the eyelid lifted up, acted in some measure like an additional muscle, by partly raising the globe of the eye. The ligament soon began to waste, and in about three weeks quite vanished.

" From having seen the two preceding instances of sight restored, and from the disappearance of this ligament, I thought the opacity of the cornea in this child too would soon begin to give way ; but in this I was deceived ; a whole year having elapsed before the smallest alteration took place.

" At the end of a year, the child seemed to be much diverted by passing its hand perpetually, with the fingers extended, before its eyes; and this has been its constant amusement from that time. The opacity has slowly diminished, but much of it yet remains.

" The child is now two years of age, but as it can find its way about the house, and distinguishes colours and different objects, by holding its head in a particular direction, I think, in time, the opacity will entirely disappear."

Deptford, Feb. 2d, 1790.

To recapitulate :—It is proved by the clearest testimony that in the younger of the two children whose cases I have described, the appearances existed within one hour of birth, and that there was not purulent ophthalmia. What clearer testimony can be obtained

respecting any disease of the eyes being congenital?

The mother was led to examine the eyes of the elder boy on the day after birth, by observing when he was asleep a prominence of the eyelid arising from the staphylomatous cornea. The staphyloma still exists, and the mother says that the eyeball had the same appearance then, except that it was not so prominent. Her surgeon saw the eyes on the same day, and obviously considered them to be incurable by medicine.

In a third case (Mr. Walker's) the child on the second or third day after birth had perfectly opaque corneæ, and not any signs of existing inflammation.

I need not remark that it is impossible to explain the last two cases on the supposition of their having arisen from purulent ophthalmia after birth.

Instead of denoting the points of resemblance between the two first of these cases and Mr. Farar's, I must devote the remainder of this communication to an examination of the following judgment which has been passed upon the latter by Mr. Middlemore, of Birmingham:—

" The occurrence of extensive opacity of the cornea, as an effect of purulent ophthalmia of newly-born infants, appears to have led Mr. Farar into a *very curious blunder.* In a paper read before the Society for Promoting Medical Knowledge, he has very singularly pointed out, as a congenital disease, what I conceive to have been a mere effect of inflammation *." (Here Mr. Middlemore quotes Mr. Farar's paper verbatim, as far as the end of the *second* case.)

Whether congenital opacity of the cornea has ever occurred, is not merely a question of curiosity, but one of practical interest. Suppose a child to be born with the appearances I have described, and that they are not observed till several days after birth, would it not be very natural for the friends to suppose it became blind whilst the doctor was seeing it daily? In defence of himself, the doctor might urge that there had been neither purulent discharge from the eyes, nor other signs of present inflammation; yet, if he turned to his own experience, and to

the literature of the subject, he would find that the cases (and those, perhaps, the only cases) that he could adduce on his behalf, are disbelieved by the only author that has noticed them—by the writer of a systematic work, whose province, as such, is to pass impartial decisions, and who, being a self-elected judge, may reasonably be supposed to have regarded the cases with the greater care before he passed judgment upon them.
